Co-Hosts of the 11th International Coral Reef Symposium

US CORAL REEF TASK FORCE

Commitment to Coral Reef Conservation:

- Leadership
- Research
- Management
- Education

The U.S. Coral reef Task Force's (USCRTF) mission is to lead, coordinate, and strengthen U.S. government actions to better preserve and protect coral reef ecosystems. The Task Force is co-chaired by the Departments of Commerce and of the Interior, and includes leaders of 12 federal agencies, seven U.S. states and territories, and three freely associated states. To implement the policies and requirements of the Executive Order, the Task Force has provided a forum for coordinated planning and action among federal agencies, state and territorial governments, and nongovernmental partners. To fulfil its mission, the Task Force developed national strategies, targeted initiatives, and new partnerships to strengthen stewardship of the coral reef ecosystems in the United States territories, commonwealths, and internationally.

STATE OF FLORIDA

With the longest coastline of the 48 contiguous states, 41 aquatic preserves and three of the nation's National Estuarine Research Reserves, Florida is undeniably an ocean state. Over the last five years, Florida has established the benchmark for ocean protection by significantly restricting offshore drilling, establishing the Tortugas Ecological Reserve, one of the largest marine reserves in the world, creating a "no discharge zone" in the Florida Keys National Marine Sanctuary and developing partnerships with the cruise ship and marine industries to improve environmental management practices. Upgrading wastewater systems and acquiring land in the Florida Keys is also protecting the third largest barrier reef in the world.

Sanctioning Organization

INTERNATIONAL SOCIETY FOR REEF STUDIES (ISRS)

Founded in 1980, ISRS is the largest society of reef scientists in the world with over 800 members. The principal objective of ISRS is to promote the production and dissemination of scientific knowledge and understanding of coral reefs, both living and fossil, for public benefit.

The ISRS produces Briefing Papers and Statements about the state of coral reefs for the benefit of the wider community. ISRS produces and distributes the quarterly scientific journal Coral Reefs containing peer-reviewed scholarly works on the geology, biology, ecology, and environmental issues regarding the world's coral reefs.

ISRS hold annual meetings, sponsors biannual conferences, and distributes the newsletter Reef Encounter, and supports students through fellowships.

ISRS sanctions the world's major coral reef science meeting, the International Coral Reef Symposium (ICRS), held every 4 years.

Mini-Symposium 24: Reef restoration
A. Edwards, B. Rinkevich, A. Moulding, R. Villanueva

Mini-Symposium 25: Predicting reef futures in the context of climate change: Is 500 ppm CO_2 and 2°C of warming the 'tipping point' for coral reefs?
O. Hoegh-Guldberg, A. Baker

Mini-Symposium 26: Biodiversity and diversification of reef organisms
A. Kerr, G. Paulay, and M. Pichon

EDITOR'S PREFACE

We proudly present you here with the Proceedings of the Eleventh International Coral Reef Symposium (11 ICRS), held at the Conference Center on Port Everglades in Fort Lauderdale, Florida between the 7th and 11th July 2008. The two proceedings volumes contain almost 300 contributions arising from this vibrant and well-attended conference – with nearly 3500 attendants the biggest one in the ICRS's proud history!

Papers encompass a wide variety of topics, stretching from geology, via biology into management science. The distribution of papers clearly reflects the evolving status of coral reef science in 2008. The sections with the most contributions are those concerning themselves with measuring the status of reefs, those dealing with resource extraction and management issues and those evaluating the impacts of man-made changes to the atmosphere and biosphere.

The load of the editorial process was carried by a great many people. The chairs of the individual mini-symposia reviewed the manuscripts in their sessions and then forwarded their recommendations to us. Those most active are named on the cover page, but most chairs carried at least some of the load. Their hard work is acknowledged on a separate cover page for each mini-symposium. Wendy Wood at NCRI spent a great deal of effort throughout the organizational process and also during final formatting, Amy Koch and Laura Checkett at Mira Digital Publications maintained the submission website and were instrumental in producing the paper and digital versions. We thank Dr. Jamie Oliver and Moi-Khim Tan of the World Fish Center for making the upload of this Proceedings to the ReefBase, and therewith its free dissemination, possible. We also thank the reviewers, too numerous to be named individually, for their crucial contribution.

Although we have done our best to produce an error-free Proceedings, undoubtedly many errors remain. We apologize for these. Hopefully the benefits of relatively rapid publication and the freedom given to authors to produce their papers as they themselves found most fitting, will outweigh the disadvantage. We hope that these Proceedings volumes will prove a valuable resource and carry forward the traditions begun in 1969 at the First such Symposium at Mandapam Camp in India. May many more follow!

Enjoy your Proceedings!

Bernhard M. Riegl
Richard E. Dodge

OUTCOMES OVERVIEW

Synopsis

A defining theme of the 11th International Coral reef Symposium was that the news for coral reef ecosystems are far from encouraging. Climate change happens now much faster than in an ice-age transition, and coral reefs continue to suffer fever-high temperatures as well as sour ocean conditions. Corals may be falling behind, and there appears to be no special silver bullet remedy. Nevertheless, there are hopeful signs that we should not despair.

Reef ecosystems respond vigorously to protective measures and alleviation of stress. For concerned scientists, managers, conservationists, stakeholders, students, and citizens, there is a great role to play in continuing to report on the extreme threat that climate change represents to earth's natural systems. Urgent action is needed to reduce CO_2 emissions. In the interim, we can and must buy time for coral reefs through increased protection from sewage, sediment, pollutants, overfishing, development, and other stressors, all of which we know can damage coral health.

The time to act is now. The canary in the coral-coal mine is dead, but we still have time to save the miners. We need effective management rooted in solid interdisciplinary science and coupled with stakeholder buy-in, working at local, regional, and international scales alongside global efforts to give reefs a chance.

Introduction

The 11th International Coral Reef Symposium concluded a marathon week (July 7-11, 2008) with over 3,500 attendees from 75 countries; 1032 oral and 1600 poster presentations; 26 mini-symposia; 3 special sessions; 20 field trips; addresses by 6 distinguished plenary speakers (Malcolm McCulloch, Joan Kleypas, Roberto Iglesias-Prieto, Robert Cowen, Drew Harvell, Daniel Pauley), the Darwin Medalist (Terry Hughes), the President of the International Society for Reef Studies (Richard Aronson), NOAA Administrator Vadm.Conrad Lautenbacher, and also by Florida's governor Charlie Crist, US Congressmen Ron Klein and Brian Baird, and Florida representative Ellyn Bogdanoff; 40 sponsorships from diverse government agencies (including Co-Sponsorships from the state of Florida, NOAA, and DOI), academic institutions, NGOs, and private industry; scores of exhibits; and a fine educational center.

The Local Organizing Committee, Super-Chairs of the 26 Mini-Symposia (scientific sessions) and President of ISRS provide this overview to highlight outcomes.

Coral Reefs Under Threat: Many Actions Can Help

Over a third of the world's coral species are at elevated risk of extinction. Reefs of the Western Atlantic have generally decreased in living corals since the 1970s, and although reefs of the Great Barrier Reef were resilient until 1996, they are now beginning to struggle. It is good news that reefs far from continents and direct human pressures, including Bermuda in the Atlantic; the Flower Garden Banks in the Gulf of Mexico; American Samoa, Fiji, Palau, and French Polynesia; and the islands of the Andaman Sea, Chagos,

and western Maldives in the Indian Ocean are still resilient and able to recover from damage. We still have some time!

The degradation and ponderous recovery of many reefs are due to combination of the global stresses of climate change coupled with regional and local stressors including runoff from agriculture, other land-based sources of pollution, over-fishing, and habitat destruction associated with coastal development.

Climate Change Effects of Warming and Acidification

Many studies have laid down stepping stones to understand ongoing changes in coral and fish community dynamics. A prime driving factor is climate change. NOAA satellites reveal tropical oceans have warmed at a significantly faster rate over the past decade. Coral cover in many locations remains low and is not recovering. This is especially true in areas that have experienced severe bleaching, a phenomenon on the increase with increasing ocean warming. Such changes are not restricted to corals. Coral loss clearly leads to loss of associated organisms; decreasing fish abundance and diversity, for example, go hand in hand with loss of corals and decreasing coral cover.

Ocean acidification and ocean warming can be thought of as the 'evil twins' of climate change. The same carbon dioxide that causes ocean warming is entering the oceans and causing chemical changes (i.e., lowered pH, lowered carbonate ion concentration) that affect marine life. Coral reefs are threatened because carbonate ions, essential for building their calcium carbonate skeletons, become less available. Reef structures are further endangered because lowered pH is likely to reduce resistance to erosion. In the naturally more acidic waters of the eastern Pacific, for example, reefs are less fortified by calcium carbonate cements and experience higher erosion rates than other reefs. It has been suggested that to save reefs, we cannot exceed 450ppm CO_2 in seawater. At the world's current rate of CO_2 emissions, we have 8-10 years to turn the tide.

There is mounting evidence that acidification can cause a slow down in the growth of corals and in coralline algae, both vital to the reef structure. Results presented at the Symposium show that calcification rates in many corals are already declining from a combination of factors including increasing temperature, decreasing water quality, and ocean acidification. In addition, ocean acidification is now shown to reduce the ability of coral larvae and coralline algae to successfully settle and grow new colonies, which will affect the ability of degraded reefs to recover through reseeding with larvae.

We can expect winners and losers in warmer and more acidic oceans, but the net result will not be stasis. Rather, it is likely that some species will not be able to maintain a foothold in the ecosystem, upsetting the normal day-to-day interactions between coral reef species, as well as the maintenance of the reef structure itself.

Scientific Advances

The Symposium witnessed many new science advances that increase our understanding about coral reef ecosystems. Several scientists used new genetic techniques to show that reefs are connected primarily at a scale of tens of kilometers (km). In contrast with previous thoughts that reefs were highly interconnected at scales of thousands of km, these studies show that only occasional pulses of propagules leave the reef 'village'. Coral larvae settle in close proximity to their parents, and some fish are homing in to local coral heads after tens of km of travel. Such local connectivity suggests that local protection and management will lead to local benefits. Action and protection also buys time for adaptation. Simultaneously we must not lose sight that important ecological connections and stressors (e.g., migration, larval transport, upwelling, pollution, pathogens, climate change) also exist at the larger ecosystem scale.

Molecular tools are revealing a diverse array of microorganisms living around and in association with reefs and able to adapt subtle environmental shifts. The microorganisms have vital roles in reef health, but if perturbed, these roles can break down in a variety of detrimental ways and lead to infection and disease. Researchers are reporting a link between coral disease and environmental change, and even viruses are now implicated in coral disease and associated coral tumors. Yet, there is also some evidence of developing immunity, whereby *Vibrio* and other bacteria that once caused harm to corals are no longer found in

association with the coral-disease. In addition, some Caribbean sea fans, seriously impacted in the first round of disease, seem to build up resistance.

Scientists are also looking at the genes that corals use to acclimate to surrounding conditions to determine how corals react to their environment. Corals can make their own sunscreen proteins and can customize their protection to light level by up- or down-regulating genes that control the protein production. Many other genes are also adjusted by corals in response to environmental cues that lead to spawning. There is a potential role in synchronization of spawning and corals may be 'talking' to each other, via chemical messengers, to help synchronize the final stages of spawning.

Some corals manage to thrive in harsh conditions such as extreme temperatures including tidal pools and in enclosed seas. Among various coping mechanisms, they may selectively cultivate particular types of symbiotic algae. The symbiotic algae that live inside corals power the latter's metabolism and skeleton formation. New insights show how the coral-symbiont relationship can improve stress resistance. Corals may be able to expel partners susceptible to heat or uv-stress, and up-regulate the population of more robust partners that were previously cryptic and barely detectable. These new algae keep the corals healthy at the higher than normal temperatures, or produce antioxidants to soak up toxic byproducts of increased chemical activity. The buildup of resilience of some reefs from previous hard knocks illustrates that we must protect not only beautiful reefs from abuse, but also the reefs in marginal conditions that may be less attractive at first sight. These might house the survivors for future generations.

Management

It is instructive that the largest of the 26 mini-symposia of the 11th ICRS was devoted to management topics. Related symposia concentrated on reef restoration, fisheries, and social ecological systems.

By 2015, half the world's population will live along a narrow band of coast, putting unsustainable pressures on coastal resources. There will be coral reefs in our future only to the extent that they are valued by people. Understanding the value of reef ecosystem goods and services can help to promote protection and thwart degradation. Economic benefits, incentives, and cultural values need to align with conservation efforts. Social scientists have much to contribute to this aspect as well as towards environmental use planning within local and regional areas

Likewise, managing reefs must include managing people's behavior toward reefs. Social science can help us understand the root causes of people's behavior, including poverty, global demand for fish products, and tourism. Rising food and fuel prices can put greater fishing pressure on near-shore reefs, while open access along the coasts of many poor countries is leading to a Tragedy of the Commons and serial depletion of fish stocks. Fisheries catches from many islands are vastly underreported, and fish populations severely depleted and in critical condition. But, through remote sensing, mapping, modeling, and decision support tools, it is possible for stakeholders to better visualize changes in reef resources, and policy makers to understand the impacts of decisions on the vital services that coral reefs provide.

Local action is one key method to achieving management success, and communities and government can be effective stewards of coral reefs once it is understood that it is in the interest of the public and individual good to do so. Linking coral reef conservation to human welfare, Healthy Reefs for Healthy People, is a useful theme to be repeated with ties to tourism, livelihoods, food security, as well as cultural and spiritual well being.

Marine Protected Areas are multiple-use areas, in which various tools, particularly zoning, are used to protected marine resources (marine reserves or no-take areas), define and confine human uses, separate conflicting activities, and consolidate administration to eliminate duplication and overlap. Studies in the Philippines and Guam, for example, show that corals inside MPAs have less disease than fished areas which have large gaps in diversity affecting affect disease transmission. MPAs represent effective management tools and work best when providing interim benefits as well as longer conservation benefits. Scientists reiterated that MPAs are necessary but not sufficient. Protection of as much reef territory as possible (ecosystem based management) recognizes that local efforts can build to regional ones which in turn can build into global ones. Organizational and scientific capacity is needed to establish and maintain

marine management areas. In some cases, hybrid designs of no-take and periodically closed areas may better address economic needs of the community and conservation objectives.

Restoration techniques are also advancing and offer promise especially where the original cause of the reef decline has been removed or addressed.

Many stressors including overfishing, run-off, and development must be addressed. A village approach, natural and social scientists, managers and local communities working together, could make it happen. Changes needed to protect the word's coral reefs include: 1) convincing communities that reefs are at risk, 2) enlisting multiple levels of public, industry and government support, 3) providing necessary legislative and regulatory powers, and 4) conducting needed science with sufficient information transfer. In this way effective management rooted in broad interdisciplinary science and stakeholder buy-in, working at local, regional, and international scales, coupled with global efforts to reduce atmospheric CO_2, will give reefs a chance.

A Call to Action for Coral Reefs

2008 is a critical time for coral reefs. At the 11th International Coral Reef Symposium held in July, midway in the International Year of the Reef, over 3,500 experts from 75 countries assembled to face some hard truths: coral reefs are teetering on the edge of survival, and it is our fault. High levels of carbon dioxide in the atmosphere can produce a lethal combination of warmer seawater and lower pH. Pervasive overfishing, pollution, coastal development, and physical damage further undermine reef health, and consequently that of the people and ecosystems depending upon them. An overview of the 2632 papers presented can be found on http://www.nova.edu/ncri/11icrs/outcomes.html

Coral reefs feed, protect, and provide livelihoods for hundreds of millions of people around the world. They create homes for billions of fish and other animals, buffer coastlines from the ravages of storms, and provide rich economic opportunities through tourism and fishing. Their value to society has been estimated at more than $300 billion/yr. Reefs are the dynamic centers of the most concentrated biodiversity on Earth. Losing coral reefs would rob the world of one of nature's most precious gifts.

Despite these challenges, it is not too late to save coral reefs. The 11th ICRS gave a renewed sense of purpose and hope for the future. A consensus emerged that society has both the knowledge and the tools to bring coral reefs back from the brink. The only question is – will we act? We have a real—but rapidly narrowing—window of opportunity in which to take decisive action. We must immediately:

- **Cut CO_2 emissions by lowering our carbon footprint and ask our policymakers to commit to low carbon economic growth.**
- **Eliminate open access fisheries in coral reef ecosystems.** Establish and enforce regulations on user rights, total allowable catch, individual catch quotas, non-destructive gear and other sustainable fisheries regulations.
- **Protect coral reef herbivores, including parrotfish.** Ban the harvesting of these species for sale and commercial consumption.
- **Establish and strictly enforce networks of Marine Protected Areas that include No-Take Areas**. Consult with local communities and authorities on design and benefit sharing to maximize returns and build sustainability into the process in order to protect marine biodiversity and restore vital fish stocks.
- **Effectively manage the waters in between Marine Protected Areas.** The enforcement of coastal zoning, environmental impact assessments and 'polluter pays' regulations can help control marine and land-based sources of pollution, while strategic environmental assessment can effectively manage coastal development and tourism.
- **Maintain connectivity between coral reefs and associated habitats**. Mangroves, sea grass beds and lagoons contribute to the integrity of reef ecosystems and their continued production of ecosystem services.
- **Report regularly and publicly on the health of local coral reefs**. Include assessments of the effectiveness of management and conservation measures.
- **Recognize the links between what we do on land and how it affects the ocean**. We live on a blue planet—our health depends on ocean health.

- **Bring local actors together to develop a shared vision of healthy reefs and a road map for getting there.** Engage members of industry, civil society, local government and the scientific community to set ambitious targets and performance indicators.
- **Work for change with management to produce desired outcome.**

Only by taking bold and urgent steps now can we hope to ensure that reefs will survive to enrich life on earth, as they have for millions of years before us. By failing to act we risk bequeathing an impoverished ocean to our children and future generations.

Sincerely,

A New Caribbean Reef Model: A View From Ye Shoulders of Giants

D. K. Hubbard[1]

1) Dept of Geology, Oberlin College, Oberlin OH 44074, USA

Abstract. For geologists, three cores from Lang Bank described at the 1977 ISRS meeting in Miami, FL set the direction of the coral-reef discussion for the next three decades. High accretion rates from this and other Caribbean sites led us to ask why reefs capable of outpacing even the fastest sea-level rise could be abandoned. A possible gap in accretion on Lang Bank at 10,000 CalBP attributed to dirty water flowing off the recently flooded bank provided a solution to this "drowning paradox", and the Lang Bank story was extrapolated to the entire Caribbean. Recent studies suggest that some of the foundational ideas upon which our models were built may warrant reexamination. *Acropora palmata* reefs not only continued to build, but thrived across the presumed Caribbean-wide gap. Caribbean reef building can generally be characterized as transgressive between 11,000 and 7,000 CalBP due to a steady and rapid rise in sea level, and regressive thereafter, as sea-level rise slowed to below 4 m/Kyr. However, two millennial-scale lapses remain for *A. palmata*, starting at ca. 6,000 and 3,000 CalBP, respectively, well after sea-level rise had slowed to below the average rate of reef accretion. Their origins remain unknown, but could bear on the species' recent decline.

Key words: Caribbean; Reef Models, Reef Accretion, Holocene, *Acropora*

Introduction

Our earliest coring studies were designed primarily to address Darwin's subsidence hypothesis. The reef and underlying limestone intervals atop the epic cores through the Marshall Islands (Ladd and Schlanger 1960) were catalogued as "reefal limestone" and set in storage once the basalt intervals that vindicated Darwin were encountered. This focus was changed by the development of a small and cost-effective drilling system that provided access to the interiors of modern reefs (Macintyre 1975). Early descriptions for the Caribbean (Adey 1975; Macintyre and Glynn 1976; Shinn 1980) were quickly followed by studies along the Great Barrier Reef (Hopley 1982; Davies et al. 1985), the Indo-Pacific region (e.g., Camoin et al. 1997; Montaggioni et al. 1997), and numerous other locales throughout the tropics.

At the Coral Reef Symposium in Miami, Adey et al (1977) described reef accretion along the southwestern corner of Lang Bank east of St. Croix in the US Virgin Islands (Fig. 1). *Acropora palmata* dominated early shelf-edge reefs that built rapidly until ca 10,000 CalBP, when the reefs suddenly died off. Adey et al proposed that the sudden demise was caused by turbid water flowing from the recently flooded bank. Water depth over the failed reefs increased as sea level rose over the ensuing 2,000 years. As the waters cleared, massive corals dominated the new reef community, now in water too deep for branching acroporids. The sequence of events at Lang Bank provided the foundation for Caribbean-wide models of Holocene reef development (Adey 1978; Macintyre 1988) that

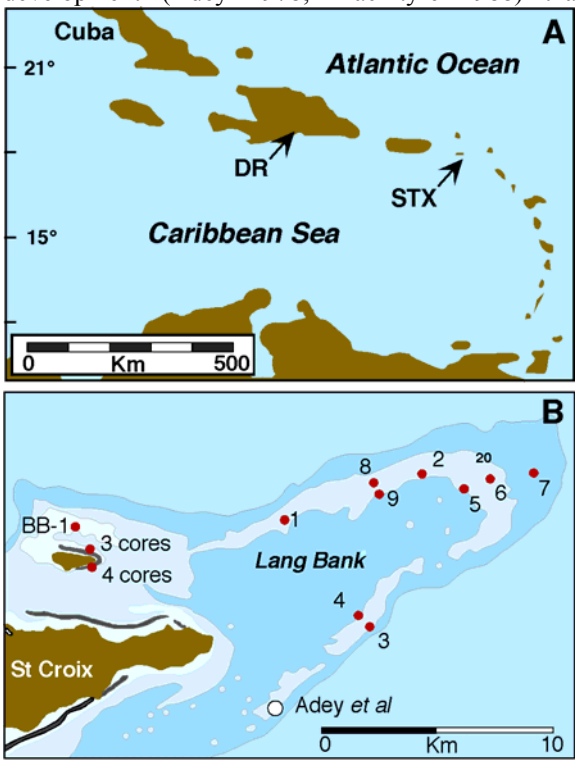

Figure 1: Location of cores (closed circles) on Lang Bank. TheSmithsonian core site described in Adey et al (1977) is shown by the open circle.

envisioned "inimical bank waters" related to platform flooding creating similar scenarios throughout the region.

This paper describes more recent core data from Lang Bank and elsewhere across the Caribbean. These data show that the interval of non-accretion within the early Lang Bank cores was largely absent elsewhere on the bank and the larger Caribbean region. An alternative and simpler Holocene Reef model based on the rate of sea-level rise and moderated accretion reef rates is proposed.

Material and Methods

On Lang Bank, four cores (LB1-LB4: Fig. 1) were recovered using a small drilling system similar to the one described by Macintyre (1875). Five additional cores on Lang Bank and eight from Buck Island were recovered using the SCARID Drilling System. In separate studies, cores were recovered from shelf-edge environments off SW Puerto Rico (Hubbard et al. 1997) and Florida (Toscano and Lundberg 1998). Cores were recovered in 1.5-m intervals, and notes during drilling permitted logging accuracy within a few centimeters. Samples were slabbed longitudinally and corals were identified to species level. Fresh-looking samples were used for radiocarbon dating, following XRD analysis to confirm their pristine nature. Methods are described in more detail in Hubbard et al. (2005).

Results

The Lang Bank cores provide a record of vigorous reef accretion around Lang Bank starting ca. 11,000 years ago (oldest ages are from Adey et al. 1977), and continuing until ca 5,000 CalBP (limited to massive corals after 6,300 CalBP). Along the northern platform margin, *A. palmata* reefs started up later (ca. 8,100 CalBP), a timing consistent with the scenario proposed by Adey et al. (1977). However, at core site LB-3 located east of the Smithsonian site (Fig. 1) reefs dominated by *A. palmata* started as early as 9,250 CalBP (i.e., in the middle of the proposed hiatus: Fig 2), and continued to accrete until 6,400 years ago. In core LB-6 on the eastern end of the bank, there is over 5 meters of reef between the Pleistocene surface and a sample that dated at 8048 ± 70 CalBP (Table 1). It therefore seems likely that both *A. palmata* and massive-coral reefs along at least the southern and eastern margins continued to build through the 10-8 Kyr interval when inimical bank waters were previously assumed to have shut down reefs all around Lang Bank.

If we examine reefs elsewhere in the Caribbean, similar patterns emerge. Reefs along the southern shelf edge of nearby Puerto Rico (e.g., PAR-11: Fig.2) were similarly dominated by *A. palmata* and

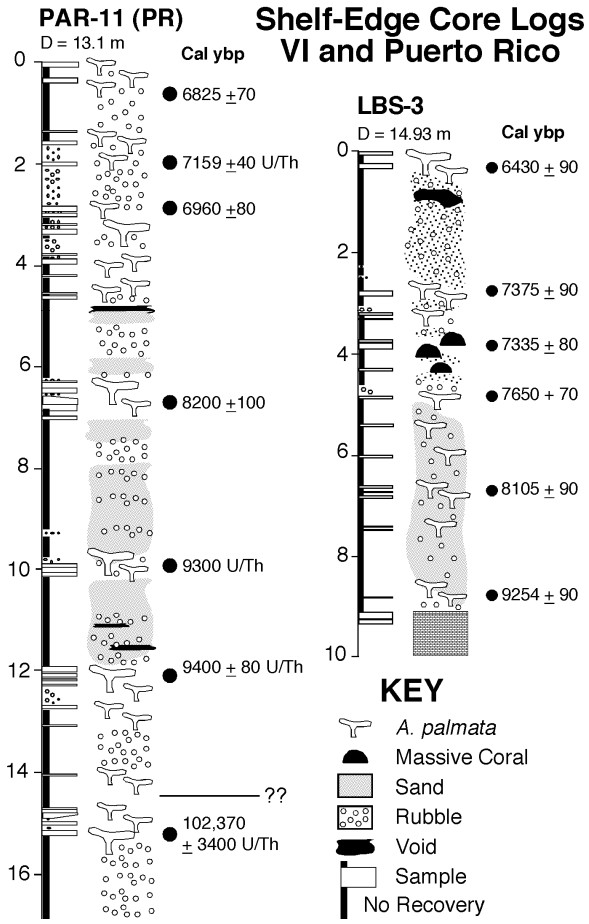

Figure 2: Core logs from the shelf edge of Lang Bank and SW Puerto Rico. Note the abundance of *A. palmata* over the interval between 10,000 and 8,000 CalBP when reefs quit at the Adey et al site. The left column shows recovery. The right log is interpreted.

continued to build through the proposed gap that was subsequently incorporated into the Caribbean reef models of Adey (1978) and Macintyre (1988).

Figure 3 summarizes the occurrence of *A. palmata* reefs over the past 11,000 years. The data are derived from a variety of water depths and reef types across a wide geographic range within the Caribbean. The number of dated *A. palmata* samples within Box A shows no significant decrease in the density of the branching species between 10,000 and 8,000 CalBP. Furthermore, *A. palmata* remained as an important component of Caribbean reefs immediately after 8,000 CalBP.

Discussion

Ian Macintyre's submersible drill provided our first real opportunity to chronicle Holocene reef history. Starting with the hallmark Panama study (Macintyre and Glynn 1976), coring investigations spread first across the Caribbean and eventually to every major tropical ocean. The earlier studies focused on the

Table 1. Lang Bank Core Statistics. All age errors are less than 100 years.

Core	Oldest	Youngest	Corals	Comments
1	6476	6215	Mixed	Not to Pleistocene

9	7145	6350	Mixed	Not to Pleistocene

internal fabric of modern reefs, with an eye toward comparisons with their ancient counterparts. The Smithsonian study on SW Lang Bank was a turning point inasmuch as it looked, for the first time, at the relationships between processes and products – relating larger-scale patterns of reef development to both local (sedimentation) and global (sea level) controls.

Citing reports of accretion rates near 10m/Kyr, Schlager (1981) argued that it was problematic that shallow-water reefs, most of which were capable of building at rates faster than the rise of Holocene sea level, could have been abandoned. He resolved this "drowning paradox" by invoking either sudden (and usually short-lived) jumps in sea level or a local deterioration of water quality sufficient to slow or kill corals. The Lang Bank story provided the best example of the impact of "inimical bank waters" related to the flooding of long-exposed shelves.

It was further argued that carbonate banks existed at similar depths throughout the Caribbean, and the scenario of early start up by *Acropora*-dominated reefs, followed by abandonment as platform tops flooded could be generalized to the region. From this, it was proposed that high-energy Caribbean shelf margins would host "relict *give-up reefs* along the upper slopes and shelf edges, and relatively young late Holocene reefs fringing most coastlines" (Macintyre 1988).

More recent data from this and other Caribbean sites do not support this scenario. Recent compilations of reef-accretion rates throughout the Holocene (Indo-Pacific and Indian Oceans: Dullo 2005; Caribbean: Hubbard 2008) show that accretion rates near 10m/Kyr are the exception and that most reefs built at half this rate or below. Hubbard (2008) computed an average accretion rate for Caribbean reefs of 3.5 m/Kyr. The long-assumed decrease in accretion with depth was not supported by the data. Furthermore, the accretion rate for reefs dominated by branching *A. palmata* (3.83 m/Kyr) was not significantly different from the rate of building for reefs with mostly massive corals (3.07 m/Kyr). This was tentatively

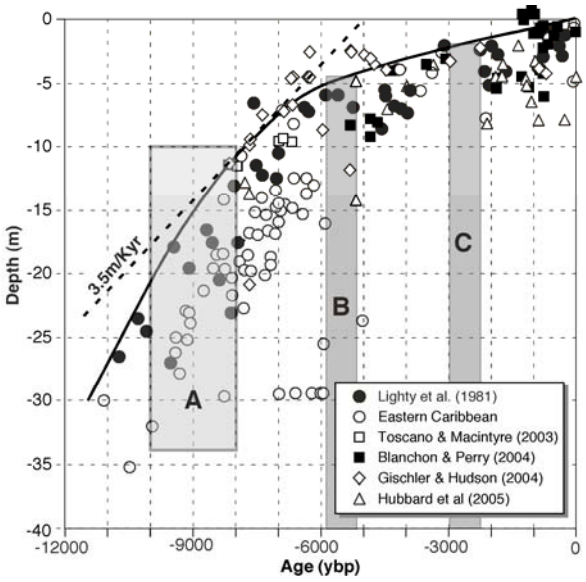

Figure 3: Summary of depth and age data for *A. palmata* in Caribbean cores (sources are provided in the legend). Box A outlines the interval across which *A. palmata* are supposed to be absent based on existing Caribbean reef models. Note that *A. palmata* not only survives but thrives across this predicted gap. Shaded intervals B and C represent times for which dated *A. palmata* samples are either rare or absent. While *A. palmata* reefs have generally occurred since 11,000 years ago, those on the left side of Box B sit near shelf margins and have not been active since ca. 6,000 years ago. Those to the right are shallower reefs, closer to shore, throughout the region. The two millennial-scale intervals of poor *A. palmata* development both occurred after sea-level rise had slowed, and some other mechanism must be invoked to explain the apparent difficulty that this rapidly growing species had encountered. The dashed line represents the average Caribbean reef-accretion rate proposed by Hubbard (2008) and intersects the sea-level curve at ca. 7,500 CalBP. Before this time, reefs would have had a more difficult time keeping up with rising sea level than after sea-level rise slowed. Modified from Hubbard et al (2005).

explained by depth-related patterns of bioerosion and down-slope transport that mirrored calcification.

If we discount the anomalously high rates cited by Schlager (1981) as typical of reef accretion, then a simpler model emerges – one that does not involve a "drowning paradox" or a need to resolve it. Figure 4 illustrates the accretion patterns for several reefs on St. Croix and Puerto Rico. Apart from a few examples, reef accretion was close to 3.5 m/Kyr and was independent of the coral species recovered in the cores.

Based on accretion near 3.5m/Kyr, early shelf-edge reefs were building at rates slower than sea-level rise. Presumably these were initially being outpaced. However, the rise of sea level was gradually slowing, and by 7,500 years ago sea-level rise and accretion were roughly balanced (dashed line in Figure 3). After this time, the balance between sea-level rise and accretion gradually reefs tipped in favor of the reefs.

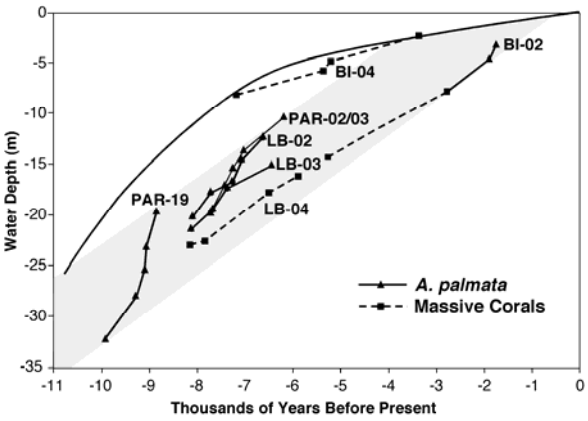

Figure 4: Accretion curves for several cores from St. Croix and Puerto Rico. These data are for single cores contained within the data base used to construct Figure 3, and most other reefs exhibited similar accretionary histories. Note that the apparent gap between ca. 8,500 and 8,000 CalBP is an artifact of the cores chosen to illustrate the accretionary pattern of eastern Caribbean reefs. Other than the deeper reef off Puerto Rico (PAR-19) and the reef constrained by sea level (BI-04), reef accretion generally conforms to the average Caribbean rate of 3.5 m/Kyr (shaded envelope). The dashed line in Figure 3 corresponds to this rate and intersects the Caribbean sea-level curve at ca. 7,500 CalBP.

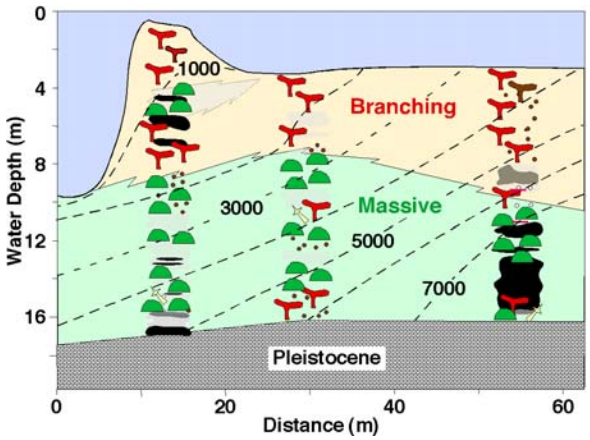

Figure 5: Cross section through the northern reef at Buck Island. Throughout its history, this reef had an accretionary potential that was greater than accommodation space being created by slowing sea-level rise. As a result, the reef built not only upward but also seaward. The initial position of this reef was roughly midway across the lagoon at a point not on this cross section. Thus, the reef has built more than 60m seaward over the past 8,000 years. Modified from Hubbard et al. (2005).

All the Caribbean shelf-edge reefs cored to date remained active after 7,500 CalBP. Based on their initial accretion rates, they should have caught up with rising sea level between 6,000 and 3,000 years ago.

Reefs that are presently emergent sit closer to shore and started up by 8,000 CalBP. Their emergence reflects the fact that sea level rose close to or slower than the reefs built. Those reefs that were at sea level (e.g., core BI-04 from Buck Island: Fig. 4) were producing carbonate faster than accommodation space was being created. As a result, they built now only upward but also seaward. At Buck Island (the small island north of St. Croix in Figure 1b) the reef that rims the eastern half of the island built seaward by more than 60m over the past 8,000 years (Fig. 5). Similar patterns have been documented for Tague Reef on northeastern St. Croix (Burke et al. 1989).

Holocene reefs exposed in the western Dominican Republic (Fig. 6) provide a unique opportunity to examine the facies architecture in much greater detail than is possible from cores. Along a 450-m long outcrop, the older section (10,000 - ~6,000 CALBP) reflects a deepening-upward sequence. In the deeper and older part of the outcrop, shallow tidal molluscs give way to massive corals and finally platy corals found at depths over 25 m on modern reefs. The shallower end of the transgressive facies bundle yielded dates as young as 5,700 CalBP (Fig. 6b), after sea level had started to slow down. Facies still deepen upward (branching → mixed coral facies). Higher (and younger) in the outcrop, the pattern is reversed, and the shallow-water branching facies builds out over the deeper mixed-coral facies (Fig. 6c) in response to even slower sea-level rise. This is analogous to the conditions seen in Figure 5 for Buck Island in the US Virgin Islands.

Collectively, these examples illustrate a simpler model for Caribbean coral-reef accretion (Fig. 7). Prior to ca. 7,500 CalBP, sea level was rising faster than shelf-edge reefs could build and they tended to gradually lag behind. By the time sea level slowed, most of them were still in water depths favorable to *A. palmata*, and reef-building gradually matched and eventually exceeded the rate of sea-level rise. Reefs closer to shore started later (9,000 – 7,000 CalBP) and in shallower water. As a result, they were able to either keep up or catch up to sea level, which they have successfully tracked ever since. As sea level continued to slow and accommodation became increasingly inadequate, these reefs have generally built both upward and seaward.

One problem emerges from all of this. As discussed above, shelf-edge reefs throughout the region should have been able to reach sea level by 4-3,000 years ago. For reasons that remain unexplained, every shelf-edge reef that has been sampled stopped accreting between 7,000 and 6,000 CalBP. This includes reefs from Lang Bank (this study), SW Puerto Rico (Hubbard et al. 1997), northern Florida (Lighty et al. 1982) and the Florida Keys (Toscano and Lundberg 1998). This occurred well after sea level slowed, and some other mechanism must be invoked – and it recurred at ca. 3,000 CalBP, again for unknown reasons. The question remains whether/how this might bear on the recent decline of *A. palmata*.

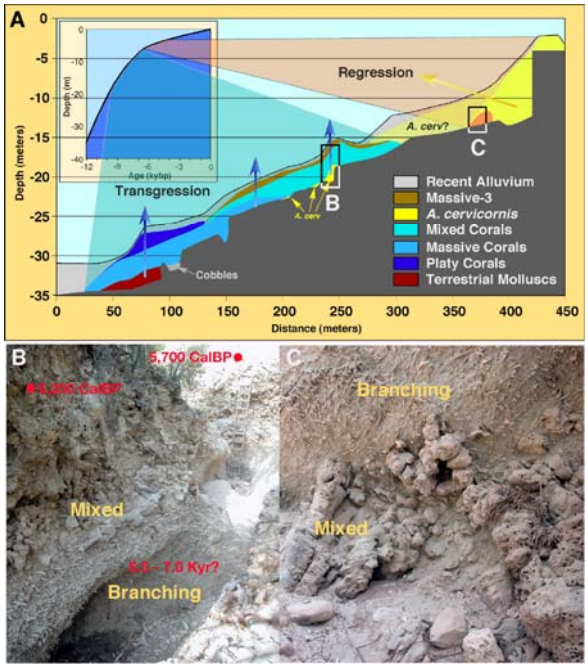

Figure 6: Facies distribution in Cañada Honda, western Dominican Republic. A) Cross section along the outcrop showing the facies distribution. Note that in the lower part of the outcrop, environments deepen upward (massive→ mixed), while in the upper outcrop the reverse occurs. Photo locations for B and C are indicated. B) Photo looking up-canyon. The sequence still deepens upward shortly after sea level has slowed down. C. Photo of a younger section near the upper end of the outcrop. Note that the section shallows upward as the branching *A. cervicornis* facies builds out over the deeper mixed-coral facies. This shift from transgressive to regressive facies architecture reflects the slowing of sea-level rise and the outbuilding of the younger section of the reef, similar to what was seen in the Buck Island reefs (Fig. 5). For outcrop location, see "DR" in Figure 1.

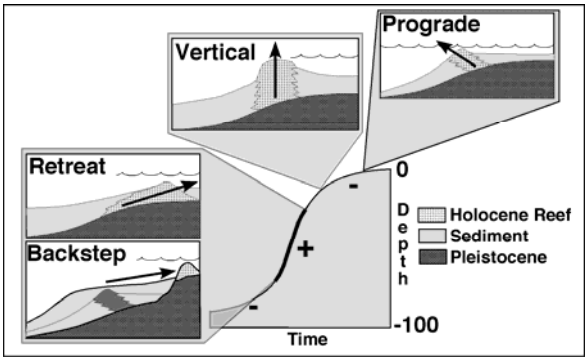

Figure 7: Facies model for Holocene sea-level rise. Prior to 7,500 Cal BP, sea level was rising at a rate faster than average accretion (+ on the curve). In this scenario, reefs either retreated upslope, backstepped (Hubbard et al, 1997) or drowned. As sea-level rise slowed around 7,500 CalBP, reefs first built vertically as accretion matched sea-level rise, and eventually started to build out over deeper mixed- and massive-coral facies (Figs. 5, 6). Presently emergent reefs closer to shore initiated as sea level was slowing, and accretionary potential quickly exceeded accommodation space. As a result, they have typically built seaward over their history.

Abstract. There is currently widespread concern about the deterioration of living reef corals, such as *Acropora*, and tropical reefs. Much of their demise appears to be related to coral bleaching, the underlying cause is probably global climatic warming. Future predictions about the responses of modern coral reefs lacks data from the geological past. The fossil record shows reef coral distributions are highly sensitive to climatic change, modulated by the availability of habitat. Here we follow the history of one individual taxon, *Acropora*, to demonstrate how a particularly important reef coral genus has responded to global change through its geological time-span. *Acropora* is the most diverse, widespread and abundant of today's tropical reef corals, with its centre of diversity in the Indo-West Pacific. Counterintuitively, it was previously absent from this region but was common in the Paleogene to early Neogene in Europe, including high palaeolatitude (48˚N) Eocene occurrences of southern England and northern France. We have assessed a unique set of unaltered, but fragmented, specimens of *Acropora* from the Eocene of the Paris and Hampshire basins for their preservational state, diagenesis, and stable isotopic composition ($\delta^{18}O$ and $\delta^{13}C$). Results suggest post-mortem parautochthonous to autochthonous deposition in low-energy embayments, with rapid burial in silty muds creating a relatively enclosed geochemical system. Taxonomic uniformitarianism and stable isotope data confirm that *Acropora* existed in tropical-like climatic conditions in Northwest Europe during the Eocene.

Key words: *Acropora*, Eocene, Hampshire Basin, Paris Basin, climate change.

Introduction

Global climatic changes, combined with regional anthropogenic processes, are combining to put modern coral diversity and distribution under threat (Hughes et al. 2003). It appears that corals are responding to such changes through acclimatisation and adaptation (Hoegh-Guldberg 1999) to occur in a broader latitudinal occurrence belt. In order to fully understand and predict the type, and magnitude, of future responses of coral reef ecosystems it is necessary to understand these changes from the geological record. Within this record, are data on the effects of both long-term and rapid climatic changes on coral reef distribution and diversity. This therefore provides a baseline, and possible analogues, to aid predictions about the future changes to coral reef ecosystems.

Much of our understanding of coral reef ecosystems from the geological past is based on taxonomic uniformitarianism, but by combining this with independent data it is possible to make higher resolution predictions about future responses. The aim of this paper is to add palaeoenvironmental context to high-latitude Eocene occurrences of the reef-building coral genus *Acropora* in order to test hypotheses on the effect of an Eocene phase of climatic warming in Northwest Europe. *Acropora* is the most successful of today's tropical reef-building corals and is presently found within the modern coral limits of ~32º north and south of the equator. The genus is found within all three major oceans of the world with a greatest diversity in the Indo-Pacific oceanic realm. Counterintuitively, *Acropora's* fossil record indicates that it originated and diversified in a North African-Mediterranean region (Wallace & Rosen, 2006, White et al., 2006, Wallace, 2008) with oldest records from the late Paleocene of Italy (Moussavian and Vecsei 1995), Austria (Tragelehn 1996) and Somalia (Carbone et al. 1994).

The localities (Fig. 1) in the Hampshire and Paris basins represent the most northerly latitudinal extent (~48ºN) of *Acropora* in its entire history. These high latitudinal occurrences coincide with a period of global warming in the Middle Eocene (Zachos 2001). During the Eocene, the Hampshire and Paris basins formed part of a larger intracratonic basin system which spanned much of southern England, the English Channel and northern France (Curry 1992).

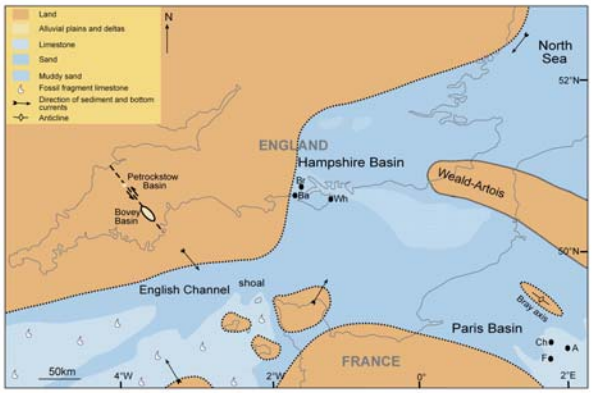

Figure 1: Palaeogeographic setting of the Hampshire and Paris basins in the Middle Eocene (Br: Brockenhurst, Ba: Barton, Wh: Whitecliff Bay, Ch: Chambers, A: Auvers sur Oise, F: La Ferme de L'Orme) (Adapted from Cope et al., 1992, & Gale et al., 2006)

The basins existed as two interconnected, shallow-marine, paralic embayments, connected to the Atlantic and with an intermittent connection to the North Sea. Cenozoic tectonic activity within the two basins included monoclinal and anticlinal folding, resulting from movement on deep-seated faults reactivated during Eocene Pyrenean compression (Lacombe and Obert, 2000). Episodic uplift of these structures led to remobilisation of Mesozoic and Cenozoic clastic sources and the creation of islands within each basin. The formation of structures such as the Weald-Artois anticline, combined with later Eocene global cooling, led to the intermittent isolation of the two basins from the North Sea followed by their Late Eocene restriction and closure. Hence the existence, both temporally and spatially, of *Acropora* in the two basins was limited and modified, not only by global, but regional and local tectonic and climatic factors.

Materials and Methods

Localities

Six localities identified by Wallace and Rosen (2006) were reviewed in this research: two Priabonian sites (Whitecliff Bay and Brockenhurst in England), two Bartonian (Auvers-sur-Oise in France and Barton in England), and two Lutetian (Chambors and La Ferme de l'Orme in France) (Fig. 1). Pristine *Acropora* specimens were available for geochemical analysis from 3 of these localities (Brockenhurst, Auvers-sur-Oise and Chambors) in the Hampshire and Paris Basins. Various sources were used for recent interpretations of the bio-, litho- and magnetostratigraphy for each locality (Aubry 1985, Gely and Lorenz 1991). Stratigraphic and geographic data is summarised in Table 1.

Fieldwork within both basins has shown *Acropora*-bearing lithologies are dominated by fine sands and muds. The associated molluscan fauna in both basins is diverse, abundant and dominantly marine although in some Hampshire Basin lithologies some of the fauna has a estuarine affinity. Other notable fauna includes sharks teeth in the Whitecliff Bay, Brockenhurst Bed and *Nummulites* in the Auvers, Sables d'Auvers Bed. Associated fauna are well preserved and have few limited borings. Reworked pebbles are found within both basin lithologies.

Specimens

71 fossil *Acropora* fragments were studied, with 11 of these used for geochemical analysis with an additional 8 of the genus *Lobopsammia* from *Acropora*-bearing lithologies. Five of the *Acropora* specimens were identified as *Madrepora*, the generic synonym extensively used by nineteenth century authors (Dana 1846). Most of the specimens are labelled as the fossil species *Acropora solanderi* (Defrance), with the rest as non-specific *Acropora.* Six of the *Lobopsammia* specimens were identified as the fossil species *Lobopsammia cariosa* (Goldfuss), with one identified as non-specific *Lobopsammia.* All *Acropora* specimens were re-identified on the basis of the taxonomic review of fossil *Acropora* (Wallace and Rosen 2006; Wallace 2008). From the Hampshire

Table 1: Summary of coral-bearing locality information from; 1. Paul Markwick (GETECH, University of Leeds), 2.Gradstein et al., 2004, 3. Various authors, 4. Fieldwork, 5. After Wallace & Rosen, 2006.

Basin localities 3 species were identified (*Acropora anglica* (Duncan), *A. bartonensis* (Wallace), *A. roemeri* (Duncan)) and from the Paris Basin 6 species were identified (*Acropora alverezi* (Wallace), *A. deformis* (Michelin), *A. ornata* (Defrance), *A. protacea* (Wallace), *A. solanderi* (Defrance), *A. wilsonae* (Wallace)).

Methods

Three approaches were used. Firstly a thorough literature review provided information about the global, regional and local palaeoenvironmental context of *Acropora* in the Eocene Hampshire and Paris basins. Secondly, fieldwork at selected locations provided detailed sedimentological and palaeoenvironmental data. Finally, a variety of quantitative and qualitative techniques (hand & thin section microscopy, x-ray diffraction, cathodoluminescence, scanning electron microscopy and stable C and O isotope analysis), allowed an assessment of preservation and diagenesis, which independently aided the palaeoenvironmental interpretation. Fossil corals often undergo post-depositional diagenesis during which secondary minerals and/or cements are deposited. The inclusion of these in any analysis may significantly affect the bulk coral trace element geochemistry of the sample leading to erroneous estimates of past climate. Petrographic and XRD enabled selection of pristine unaltered skeletal aragonite for stable isotope work.

Stable isotope analysis of $\delta^{18}O$ and $\delta^{13}C$ ratios in carbonates enabled inferences to be made about changes in environmental conditions with oxygen isotope ratios reflecting variables such as temperature and global ice-volumes (e.g. Patterson 1998; Tripati et al. 2004), while the isotopic signature of carbon may be used as a proxy for metabolism and reproduction (Patterson 1998; Patterson 1999). Powdered carbonate samples were obtained using a computer controlled micromill with samples being taken along linear transects along the axial corallite. Stable isotope mass spectrometry was performed at University College London using a Thermo Delta GASBENCH Mass Spectrometer. Isotope values are reported in per mil V-PDB (‰) with respect to modern ocean water (‰).

Results

Morphology and taphonomy

A comparison between the preserved morphological features of a modern and Eocene *Acropora* specimen confirmed the exceptional preservation of the Eocene specimens. Thin section and scanning electron microscopy of fossil specimens identified intact morphological features including axial corallites, radial corallites and coenosteum (Fig. 2a & b). All specimens show axial corallite apices with some distinguishable radiating septa. Radial corallites are identifiable with variations in costate or reticulate coenosteum (Fig. 2c & d). Selected specimens show radial corallites abraded flat against the main wall structure (Fig. 2b). In thin section multiple pristine microstructures were identified (Fig. 2a). Primarily, the aragonite composition is shown by the brown colouration of the skeleton with fanning, elongate trabeculae. The coenosteum exhibits a porous nature with large void-rich areas. Axial and radial corallites are recognised by large elongate voids and elongate septal remnants, particularly in the axial corallites.

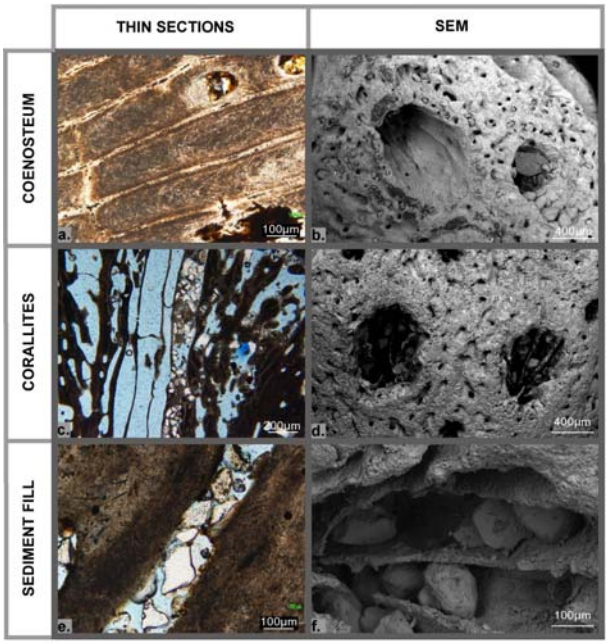

Figure 2: Summary of preservation and diagenetic features identified using thin sections and SEM. a. Characteristic trabeculae structure of skeletal aragonite. b. Highly porous coenosteum with sediment infilling. c. Axial corallite identified by elongate septal remnants and void areas. Fine grained sediment infilling corallite, mostly subangular-angular monocrystalline quartz. d. Radial corallites with remanent septal structure and sediment infilling. e. Fine grained sediment infilling void areas. f. Sediment fill within septal structure of a radial corallite.

Due to the exceptional preservation and limited fragmentation of some of these specimens, evidence of colonial types can also be seen. The Hampshire Basin specimens show variations of the four main colonial growth forms; tabular, arborescent, digitate and hispidose (Wallace 2008), and in the Paris Basin three growth forms; arborescent, digitate and tabular. Another morphological distinction between the specimens in each basin is the branch thickness. Specimens of *Acropora anglica* and *A. roemeri* from the Hampshire Basin have a sturdier growth form than species from the Paris Basin, with an average branch

thickness of 1.16 cm and 0.79 cm respectively for all species found (Fig. 3). Another significant difference is the larger amount of infilling sediment in the Hampshire Basin specimens probably reflecting the finer grained nature of the lithology from the Hampshire Basin and the larger void structures produced by the larger, coarser skeletal structures in specimens.

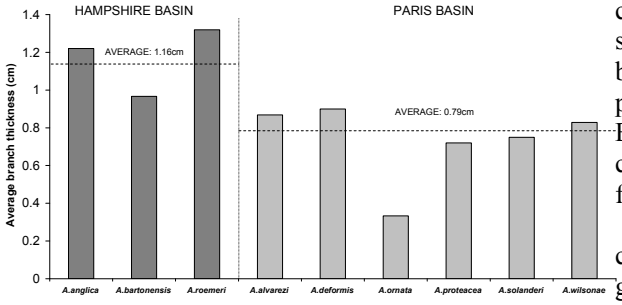

Figure 3: Variation in branch thickness shown between each species, and overall between the two basins (n=71)

Skeletal mineralogy; preservation, diagenesis and infilling

Preservation of original skeletal aragonite mineralogy is highly unusual due to the chemical instability of aragonite and its frequent alteration to secondary calcite. The combination of various methods has shown the exceptional mineralogical preservation and lack of taphonomic alteration of specimens from coral samples from both basins.

Using X-ray powder diffraction, over a 25° to 37° 2θ range, the majority of samples recorded seven main peak intensities. The main carbonate mineral peaks were four aragonite peaks (3.396Å, 3.273Å, 2.700Å, and 2.481Å) and one calcite peak (3.035Å). In addition to these, one quartz peak (3.343Å) and one gypsum peak (2.867Å) were recorded. Three samples show no peak for calcite (below 1% detection limit) and can be regarded as 100% aragonite with respect to their carbonate mineralogy.

Peak height analysis allowed the ratio for aragonite peak intensity to be determined. For *Acropora* specimens these ranged from 0.8299 ± 0.04 to 1 ± 0.05, with a maximum of 1. For *Lobopsammia* specimens these ranged from 0.9770 ± 0.05 to 1 ± 0.05. From this, the Milliman (1974) calibration curve allowed these values to be converted to percentage aragonite with respect to calcite. For *Acropora* specimens the percentage aragonite ranged from 92.55% ± 1.8 to 100%.± 2.2, and for the *Lobopsammia* specimens from 98.88% ± 2.1 to 100% ± 2.2.

The additional peaks seen in XRD across the 25° to 37° 2θ range, representing quartz and gypsum, are from infilling sediment or surface weathering (gypsum). In thin section and SEM, the quartz is seen infilling voids within the coral fabric together with minor components of clinopyroxene, biotite, glauconite and chert (Fig. 2e & f). The grains are subangular to subrounded and infilling corallites trapped particularly by intact septal structures.

All the *Acropora* specimens show some degree of cementation. The combination of thin sections, XRD, SEM and CL techniques indicates this as a minor component and confined to specific areas of the specimen. In thin section and CL there is evidence of both early aragonite cement and later calcite cement precipitation, infilling and lining porous areas. Bioerosion is minor with two of the *Lobopsammia* corals showing boring molluscs identified by their foliated internal structure.

In summary post-depositional modifications of the coral skeleton include entrapment of glauconitic fine grained sands and the precipitation of aragonite and calcite cements within the porous skeletal structure.

Stable Isotopes

For *Acropora* specimens the total variation is about 1.5‰ between -6.84‰ to -5.31‰ for $\delta^{18}O$ (Fig. 4). The range of $\delta^{13}C$ is between -4.17‰ to -1.63‰, showing a total variation of about 2.5‰. For *Lobopsammia* specimens the total variation is about 1.0‰ between -5.90‰ to -4.86‰ for $\delta^{18}O$ (Fig. 4a). The range of $\delta^{13}C$ is between -3.92‰ to -0.79‰, showing a total variation of about 3.1‰.

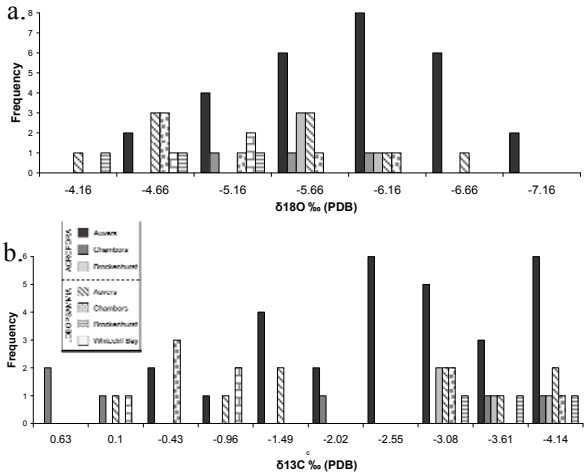

Figure 4: Frequency Histogram showing the distribution of a) oxygen and b) carbon isotope ratios for each locality of both Acropora and Lobopsammia specimens (n=60)

Carbon shows the larger variability in isotopic values, probably a function of the multiple factors which can effect this value (e.g. Zachos, 2001) (Fig. 4b). The *Acropora* specimens show a wide distribution with a skew towards isotopically lighter values. The *Lobopsammia* specimens show a weaker trend with a similar wide distribution of isotopic

values over a comparable range to *Acropora* specimens.

Discussion

Acropora is presently found within the modern reef coral limits, in all three major oceans of the world. The genus exists in a wide range of depths, reef zones and hydraulic regimes, primarily reflecting its ability for rapid growth. The fossil record shows that *Acropora* existed up to ~49 degrees north during the Eocene in the Hampshire and Paris basins. It is envisaged that in both basins *Acropora* occurred within isolated thickets/colonies, possibly forming more laterally extensive veneers, such as those seen in the marginal settings of Brownard County, Florida (Perry and Larcombe 2003). The relatively sparse distribution of specimens, and preservation as broken fragments in fine grained clastic sediments indicates that active reef accretion or mass reefal build-ups were unlikely to have occurred in either basin. If these specimens were derived from a reefal structure then unusually high hydraulic conditions would be needed to demolish evidence of this structure but to selectively preserve a limited number of pristine specimens. Additionally, the dominance of zooxanthellate and solitary corals, in modern settings typifies marginal environments, and the lack of other reef-building biota supports the absence of any reef.

The palaeoenvironmental settings are different within the two basins. In the Hampshire Basin, corals are found within siliciclastic storm beds in a relatively protected mid-shelf environment, below-wave base. Corals in the Paris Basin are found within predominantly carbonate-dominated beds and a mid-ramp environment is inferred. *Acropora's* ramose, branching habit renders the skeletal remains subject to fragmentation, through bioerosion, hydraulic energy, and rolling and abrasion by transportation. However, the preservation of these fragments, up to 4cm in length, with intact morphological features, supports a lack of transportation and reworking of the fossils. The lack of abrasion features shown by specimens from both basins indicates minimal transportation implying low hydraulic energy, protection from bioerosion and additionally rapid burial. Morphologically the sturdier growth forms come from the Hampshire Basin implicating higher wave energy in this basin relative to the Paris Basin

The pristine morphological and mineralogical preservation, and lack of bioerosion, of the specimens from both basins supports rapid burial following fragmentation of the coral branches. This infers high sedimentation rates. Rapid rates of sedimentation were required to produce a geochemically enclosed system and sufficient burial to prevent bioerosion by benthic organisms. Post-depositional modifications of the coral skeleton included entrapment of glauconitic sands and the precipitation of early aragonite and later calcite cement within the porous skeletal structure.

On the basis of modern distribution of zooxanthellate corals, the presence of *Acropora* within the two basins suggests tropical conditions persisted in Northern Europe during the Middle to early Late Eocene. This is supported by other palaeoclimatic indicators such as palaeobotanical studies (Collinson and Cleal 2001). This is confirmed by oxygen stable isotope values on specimens from basins indicating sub-tropical to tropical palaeoenvironments and the higher variation in carbon values reflecting the paralic environment in both basins.

The absence of reef rock and the existence of thickets and possible coral carpets suggests there was a lack of coral framework and raises the question as to whether this was a flourishing coral community or a disturbed/restricted state of development. The distribution of *Acropora* in the Hampshire and Paris basins during the Eocene is believed to have been at its northern limit. Combined with evidence that *Acropora* left these basins in the Late Eocene, existed for a geologically short period in each and that subsequently its northern limits retracted southwards suggests that this was a marginal setting. The lack of reefal build-ups however may have been due to evolutionary control rather than an ecological one as *Acropora* has not been found dominating reef frameworks until the Oligocene in Greece (Wallace and Rosen 2006).

In summary, the primary control on *Acropora*, and other coral genera, spatial and temporal distribution was primarily influenced by global and regional eustatic sea-level fall, climatic deterioration and local tectonics isolating both basins. Secondary controls included sediment supply and water movement. The existence of *Acropora* in the two basins reflects global climatic warm periods of the Eocene, its distribution reflects a complex interplay of local and regional factors. Global climatic and regional tectonic effects resulted in the loss of *Acropora*, and other corals, from the two basins by the end of the Late Eocene.

Enigmatic Coral Rock Pillars – Another Look into Reef Dynamics

H. Schuhmacher[1], R. Krone[2], P. van Treeck[1]

[1]Department of Hydrobiology, University Duisburg-Essen, 45117 Essen, Germany
[2]Division Marine Animal Ecology, Alfred Wegener Institute for Polar and Marine Research, 27568 Bremerhaven, Germany

Abstract. Stone capped calcareous pillars, rising 10-70 cm above the surrounding reef surface are to be found at Aqaba (Jordan) and on several other fringing reefs of the Northern Red Sea from intertidal down to 3 m depth. Terrigenous (non-calcareous) cobbles and boulders are fixed on top of coral limestone. At Aqaba it is assumed that the stones were once introduced by fishermen and came to rest in depressions of the reef. Afterwards the surrounding reef limestone was eroded so that only the substrate underlying the granite stones has been left as singular towers. ^{14}C-dating of a column sample provided an age of 345-560 years. Several interpretations are possible: the respective reef part did not grow since then, or younger layers were removed by bioerosion. Some suggestions are provided based on erosion data of sea urchins (*Diadema setosum*) and fish, gathered at that site. Two more examples of partial reef decline are presented from a reefflat at the Sinai coast north of Dahab indicating uplift along the margin of the Gulf of Aqaba and from the bay Marsa Bareika at the southern tip of Sinai where big boulders are interpreted as ballast stones discharged in an antique harbour.

Key words: Long-term reef shaping, bioerosion, Gulf of Aqaba (Red Sea)

Introduction

Some reefs at Aqaba (Jordan, Northern Red Sea) are under observation since 1972 (Mergner and Schuhmacher, 1974). They exhibit contrasting aspects from thriving coral communities with up to 60% living cover to barren limestone rock. The latter one is cleared by grazing fish and sea-urchins, especially *Diadema setosum*. Stone capped limestone pillars which rise 10-70 cm above the surrounding reef surface caused us to take a closer look at these structures and their history.

Similar structures found in other parts of the Red Sea are also shown.

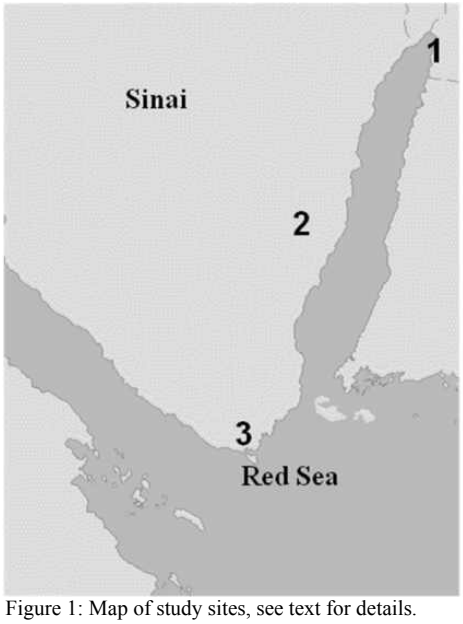

Figure 1: Map of study sites, see text for details.

Results and discussion

Findings from three sites of the Northern Red Sea are presented (Fig. 1):

1. Aqaba (northern end of the Gulf of Aqaba),
2. East coast of Sinai Peninsula between Dahab and Abu Galum,
3. Marsa Bareika, Ras Mohamed National Park, southern tip of Sinai.

In each case terrigenous cobbles and boulders are fixed on top of columnar elevations carved out from coral limestone.

Case study Aqaba:

Fig. 2 shows the top of a forereef mound at approx. 10 m depth off the Marine Science Station Aqaba. The arrow points to one of the cobblestones. The underlying pillar was identified as remnant of a *Porites* colony (Fig. 3). Its ^{14}C-dating revealed an age of 453 +/- 107 years. A neighbouring column made of a faviid skeleton was dated as to a maximum of 50 years.

It is assumed that the stones were once introduced by fishermen and came to rest in depressions of the reef. Afterwards, the surrounding reef limestone was eroded so that only the substrate underlying the granitic stones was left as singular towers. It is unknown when the stones were introduced, therefore several interpretations are possible: The respective reef part did not grow since decades/ages, or younger layers were removed by bioerosion, before the stone fell down. There is considerable bioerosion at that site: The density of *Diadema setosum* is 1.2 ind m^{-2}; the removal of carbonate substrate was calculated from gut contents and faeces analyses (considering

reworked material) as 1.023 kg m-²yr^{-1} (Kroll 1995, Reinicke and Schuhmacher 2008). Grazing fish, especially the acanthurid *Ctenochaetus striatus*, removed 1-3 mm yr^{-1} from *Favia* skeleton tiles which were exposed as colonization plates (v.Treeck et al. 1996 - regarding the impact of *C.striatus* see also Schuhmacher et al., session 10, this volume).

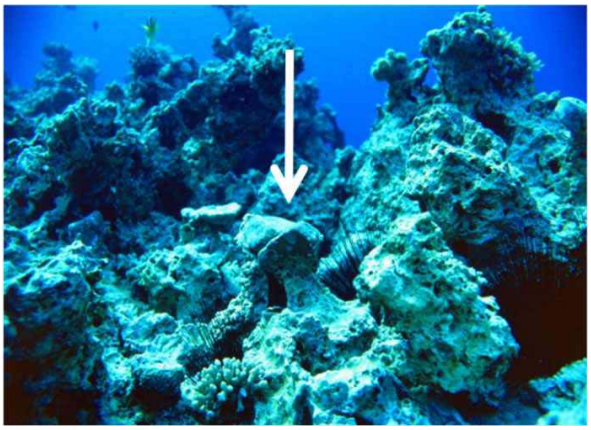

Figure 2: Granite stone on top of a forereef mound, Aqaba.

Figure 3: Stone capped *Porites* column; scale bar 7.5 cm.

Example case Sinai coast:

The mountains between Dahab and Ras Abu Galum steeply slope into the Gulf allowing development of only a narrow fringing reef. The reef flat continuously receives rubble tumbling down from the adjacent mountains. Fig. 4 shows the reef flat at low tide. At high tide the boulders are immersed except those on the tallest sockets. From the height of the calcareous columns it can be concluded that a 30-50cm thick layer was removed from the reef flat. The fact that the recent reef surface reaches to low tide level indicates a still considerable uplift of the western margin of the Gulf of Aqaba graben. Specific agents of bioerosion and time scales were not investigated.

Figure 4: Reef flat at low tide with terrigenous debris.

Example case Marsa Bareika:

Marsa Bareika is a large bay at the southern end of Sinai. A slightly inclined sandy wadi (river bed) enters the inner bay from the north. A poorly developed reef is interrupted by sandy areas. Several limestone outcrops, crowned by heavy boulders represent hardbottom islets that are sparsely colonized by corals (Fig. 5-6). The present topography does not provide an indication how the big boulders got to the site; anthropogenic transport, however, is likely. The bay is a natural harbour (today small vessels of the Ras Mohamed National Park are moored here). It is assumed that in ancient times (perhaps 2-4000 years ago) ships anchored at this site and dropped ballast stones – probably in exchange for copper or other minerals which were mined on Sinai and shipped to Egypt and further south. For a hypothetical bottom profile of that time see Fig.6. Archaeological studies have yet to be conducted. It would be intriguing to investigate ecological conditions and time periods, when this reef body formed and faded.

Figure 5: Boulder on top of a 70 cm high socket of reef rock.

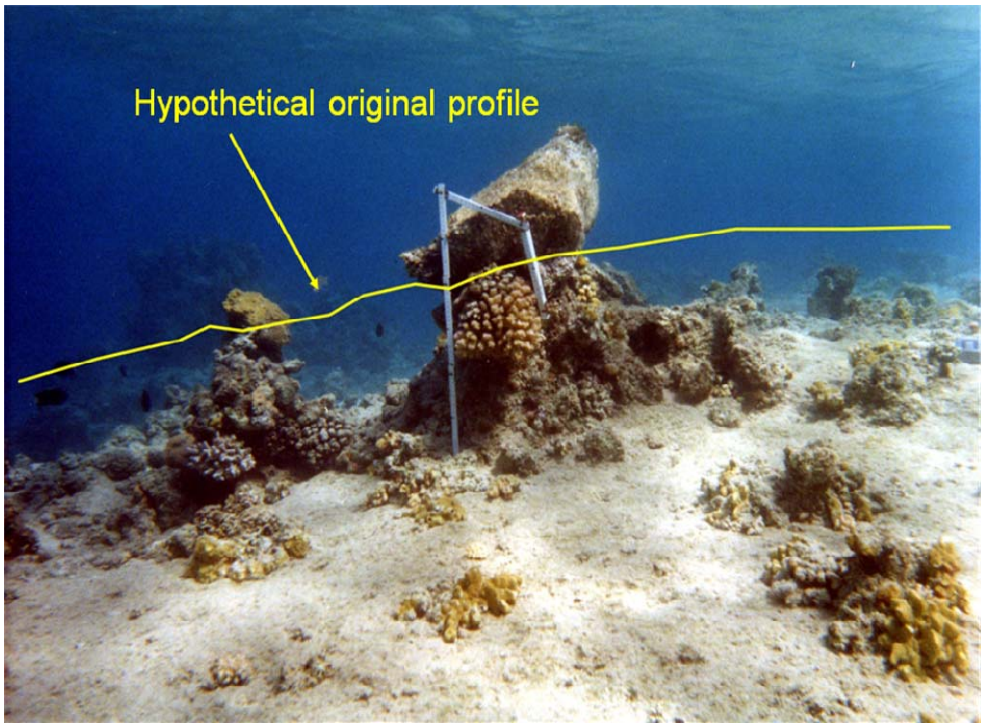

Figure 6: Boulder capped remnants of a former reef.

Conclusion

All three examples show reef areas, where the reef framework is eroding. The stone capped towers are remnants wittnessing of former reef developments. Anthropogenic reasons for the decline of these reef parts can be excluded. This presentation is thought to sensitize for this phenomenon at other places and to generate discussion about circumstances and modes of bioerosional reef shaping.

Cenozoic Evolution of Larger Benthic Foraminifers: Paleoceanographic Evidence for Changing Habitats

P. Hallock[1], L. Pomar[2]

1) University of South Florida, College of Marine Science, 140 7th Avenue S., St. Petersburg, FL 33701, USA
2) Universitat de les Illes Balears, Departament de Ciencies de la Terra, E-07122 Palma de Mallorca, Spain

Abstract. The ever-increasing treasure-trove of paleoceanographic data relating to evolving Cenozoic ocean structure, including geographic and bathymetric gradients, provides novel insights into long-term changes in environmental conditions influencing shelf, ramp and oceanic-platform habitats occupied by carbonate-producing ecosystems. Similarly, recent studies documenting the influence of internal waves on mid- and deep-shelf habitats provides equally exciting insights into previously unrecognized environmental variability experienced by organisms living in those habitats. Paleocene-Eocene photic-dependent carbonates were dominated by calcitic coralline red algae and larger benthic foraminifers (LBF), with aragonitic corals and calcareous green algae more restricted temporally and spatially. Morphologies of LBF are strongly influenced by light availability and water motion, with larger, flatter and more fragile shapes characteristic of lower light, low wave-energy environments. Since substantial LBF habitat is at middle to outer shelf or ramp depths (i.e., ~30 to ~130 m), understanding the influence of internal waves on these habitats as oceanic thermal gradients developed through the Cenozoic can provide crucial insights into evolving environmental conditions where the most diverse and highly specialized LBF biotas occurred.

Key words: Carbonate ramp, reef, internal waves, thermocline gradients, symbiosis

Introduction

Understanding biological and geochemical processes associated with modern carbonate systems is essential to interpreting fossil reefs and carbonate sedimentation. Recognizing the limitations of uniformitarianism is equally crucial (Pomar & Hallock 2008). Cenozoic carbonate-producing ecosystems emerged from the remnants of Cretaceous biotas, evolving in the warm alkaline oceans of a Greenhouse world, then modifying as Icehouse conditions developed. The latter included stronger latitudinal and bathymetric temperature gradients, declining atmospheric CO_2 concentrations and declining calcium concentrations and alkalinity in the oceans.

Paleocene-Eocene photic-dependent carbonates were dominated by calcitic coralline red algae and larger benthic foraminifers (LBF), with aragonitic corals and calcareous green algae more restricted temporally and spatially. In this paper, we compare Hottinger's (1998) synthesis of records of diversifications and extinctions of Cenozoic LBF lineages in the context of published evidence for changes in ocean circulation and thermocline structure as Icehouse conditions developed (e.g., Lear et al. 2000). Moreover, given that much of the diversification was at middle to outer shelf depths (i.e., ~30 to ~130 m), synthesizing emerging records of the influence of internal waves at those depths (e.g., Wolanski et al. 2004; Leichter et al. 2005) with the records of oceanic thermal gradients through the Cenozoic (e.g., Dutton et al. 2005) can provide crucial insights into how environmental conditions changed for middle and outer shelf benthic habitats.

Larger Benthic Foraminifers (LBF)

The LBF are an informal group of benthic foraminifers characterized by relative large size (e.g., generally > 1mm and up to 6 cm in diameter – Lee 1998) and complex internal morphologies. Modern representatives host a rich variety of algal endosymbionts in a relationship similar to that between corals and their zooxanthellae. By analogy, fossil LBF are interpreted to also have hosted algal symbionts (e.g., Lee 1998; Hallock 1999; and references therein).

Extant LBF worldwide belong to members of six long-ranging families, the Amphisteginidae, Alveolinidae, Nummulitidae, Peneroplidae, Rotaliidae, and Soritidae (e.g., Hallock 1999). One other family, the Calcarinidae, is characteristic of the late Neogene in the Indo-west Pacific, where some species are prolific producers of beach sands (e.g., Hohenegger 2006). Amphisteginidae, Calcarinidae, Nummulitidae and Rotaliidae are all families in the order Rotaliida, and are characterized by relatively transparent (i.e.,

hyaline) calcite shells. Members of these families typically host diatom endosymbionts. In contrast, the other families are Miliolida, whose shells of randomly arranged calcite crystals covered by a veneer of brick-like crystals impart a porcelaneous appearance that is relatively opaque to light (e.g., Debenay et al. 2000). The shells of many of the larger miliolids have thinned outer walls to permit light into the chamberlets. Larger miliolids host a diversity of algal symbionts (e.g., Lee & Anderson 1991). The Alveolinidae host diatoms. One lineage of Peneroplidae hosts rhodophyte symbionts while a second lineage has chlorophyte symbionts. Similarly, one lineage in the Soritidae hosts dinoflagellate symbionts while the second hosts chlorophytes.

Distributions of modern taxa of LBF are strongly influenced by light (Fig.1). Both between species and within species trends in morphology, especially shape and surface-to-volume ratios, reflect light intensity and water motion (e.g., Hohenegger 2005), both of which influence rates of calcification (e.g., Hallock et al. 1986). Thus, both conceptual (Hallock & Glenn 1986; Beavington-Penney & Racey 2004) and numerical (e.g., Hallock 1987; Mateu-Vicens et al. 2008) models have been developed to interpret paleoenvironments of LBF-rich limestones.

Hallock (1988, 1999) also noted that some taxa, notably the porcelaneous Soritidae and the stellate Calcarinidae, have tended to diversify "laterally", specializing to different relatively shallow-water, higher light habitats, while modern Amphisteginidae, and Nummulitidae have diversified vertically, with robust shapes characteristic of shallower dwelling species and flat shapes characteristic of deeper depths.

Historically, the terms photic or euphotic have been used to describe environments where there was sufficient light for an excess of photosynthesis over respiration (e.g., Hallock & Schlager 1986). Pomar (2001) proposed terminology to distinguish among photic habitats. He used "euphotic" only for depths where light is sufficient for high rates of photosynthesis and associated hypercalcification, typically less than 30 m even in very clear water. He used "mesophotic" to characterize depths where light is sufficient for photosynthesis to support substantial calcification rates, but not true hypercalcification, i.e., depths in the 20-70 m range, again dependent upon water transparency. He used the term "oligophotic" to characterize depths where there is limited light penetration sufficient to support calcifiers like coralline red algae, and very thin flat LBF and corals. As Hallock (1987) demonstrated using a modeling approach, well developed biotas adapted to low light for photosynthesis depend upon consistently high water transparency that permits light penetration to depths >70 m. Such consistently high water transparency only occurs where surface waters are sediment free and have extremely low nutrient and plankton concentrations.

LBF assemblages typically characterize Pomar's (2001) light-defined zones (Fig. 1). Most of the miliolid LBF, as well as most calcarinids, live primarily in euphotic habitats. On the Florida reef tract, Soritidae (especially the Archaiasinae) show depth zonation, but none are common below about 30 m. Worldwide, robust *Amphistegina* also are found abundantly at less than 30 m, with progressively thinner or smaller chambered morphologies dominating below 30 m. Nummulitids can be found at less than 30 m, but most dominate at mesophotic to oligophotic depths (>30m, see Hohenegger 2005). Several extant nummulite species, whose shapes are very thin and flat, have depth distributions that peak at 70 m or deeper.

Water motion is another important environmental parameter influencing LBF distributions. Both wave energy and light decrease exponentially with depth, and both influence shell morphologies similarly, which is one reason LBF are excellent paleodepth indicators. Lenticular shapes, thicker shell walls and, in the case of the calcarinids, stellate morphologies allow such foraminifers to thrive and hypercalcify in high light, high wave-energy environments such as reef flats of the Indo-Pacific.

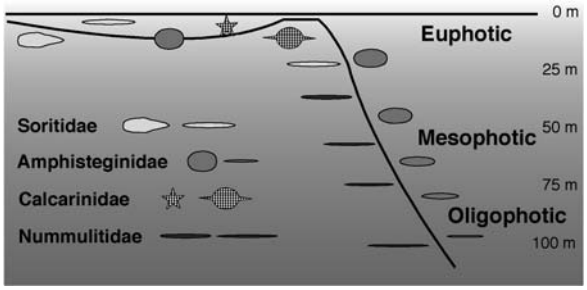

Figure 1: Major families of larger benthic foraminifers illustrating shapes and general depth ranges (Hallock 1999) in the context of euphotic, mesophotic and oligophotic habitats as defined by Pomar (2001).

In contrast, discoid morphologies are best adapted to quieter environments, where they either burrow their apertural face into the surficial sediments at a low angle, leaving most of the dorsal surface exposed to light, or sit flat on the substratum. Either way, they are superbly adapted to harvesting food and dissolved nutrients from the substratum and pore waters, while their algal symbionts capture radiant energy from sunlight. If their habitat is infrequently disturbed, e.g., by storm waves or deposit-feeding animals, these foraminifers can literally spend years accumulating the sparse resources required for reproduction (Hallock 1985). Exceptions to this generalization for discoid morphologies are shallow-dwelling Soritidae

that commonly attach to hard or phytal substrata in reef-flat environments.

Costs and benefits of algal symbiosis

There are energetic costs to establishing and maintaining symbioses between heterotrophic hosts and photoautotrophic symbionts (e.g., Hallock 1981; Stoecker 1998). Unless environmental conditions tip the energy balance in favor of benefits of symbiosis, photoautotrophic and heterotrophic taxa will predominate. The energy from photosynthesis must provide more than half the energy needed by the holobiont to be beneficial (Stoecker 1998).

Hallock (1981) predicted that, under nutrient-poor conditions with sufficient light, algal symbiosis can provide literally orders of magnitude energetic advantage over autotrophic-heterotrophic strategies. She further postulated that the most advantageous conditions for algal symbiosis occur when essential nutrients are extremely scarce and the only concentrated forms available are in particulate organic carbon such as plankton, bacteria or organic detritus.

Hallock (1985) examined life history strategies that would be most advantageous for LBF. She concluded that hydrodynamic environments, which tend to also be high light environments, would favor faster growth, higher fecundity and relatively short life spans. In contrast, Hallock (1985, 1987) predicted that, in mesophotic to oligophotic environments where radiant energy is limited but the probability of disturbance by hydrodynamic events is much reduced, longer life spans and production of fewer, larger embryons are advantageous. Mesophotic conditions appear to be optimal if water transparency is relatively dependable, because the holobionts are still able to get substantial energy from photosynthesis, while the potential for either photo-oxidative stress or physical damage by hydrodynamic events are low. The greatest risk is the potential for insufficient sunlight during turbidity events, although there is the potential for energy supplementation from feeding. Interestingly, the two extant families most prevalent in mesophotic and oligophotic depths are the amphisteginids and nummulitids. The former can become dormant within 24 hours of darkness, while at least some of the latter are bacteriovores (Lee 1998).

Oligophotic environments tend to be low energy, both radiant and hydrodynamic. So the limiting factor must be the tradeoff between the energy required to support the symbiosis versus the energy gain from photosynthesis. The morphological investment in maintaining a symbiosis appears to be extreme in very low light environments – long lives spent producing extremely large, flat shells. The strategies appear similar for zooxanthellate corals in oligophotic environments: significant investment in structures that optimize light capture rather than food capture (e.g., Jarrett et al. 2005). As a consequence, light energy must be relatively predictable for the investment to be beneficial, requiring that water column transparency be consistently very high.

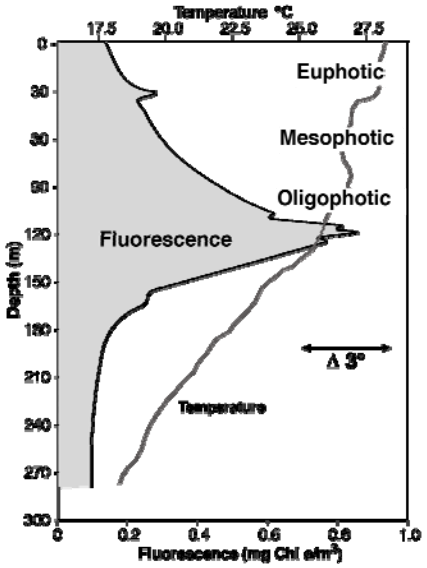

Figure 2: Data from Hallock et al. (1991) showing surface-to-thermocline temperature and fluorescence gradients for the modern northern Caribbean, annotated to indicate changes in light and temperature in the upper 150 m.

Bathymetric gradients and internal waves

In modern subtropical and tropical oceans, outside of upwelling zones, surface waters are warm and generally relatively well mixed by winds down to roughly 100 m. The base of the mixed layer/top of the thermocline also corresponds to the top of the pycnocline and nutricline, as well as the chlorophyll maximum zone (Fig. 2). In addition, O_2 concentration declines and pCO_2 increases relatively rapidly with depth. Above this layer, there is sufficient light for photosynthesis but generally limited nutrients. Below there is minimal light, but more organic carbon and biological activity utilizing oxygen, releasing nutrients and CO_2. This zone is very biologically and chemically dynamic.

The base of the mixed layer and uppermost thermocline corresponds with deeper mesophotic to oligophotic conditions described for outer shelf and ramp biotas. Thus, changes in physical and chemical conditions along that gradient would strongly influence deeper dwelling LBF biotas. The final consideration here is the influence of internal waves on LBF in mesophotic and oligophotic environments.

Leichter and colleagues studied internal waves in Jamaica and the Florida Keys, recording substantial temperature fluctuations on tidal frequencies at depths below about 30 m (e.g., Leichter et al. 2005; Leichter

& Genovese 2006). Wolanski et al. (2004) recorded temperature variations with depth in Palau, where strong internal waves impart as much as five degrees of temperature variability on habitats between 30 and 100 m depth on tidal cycles (Fig.3).

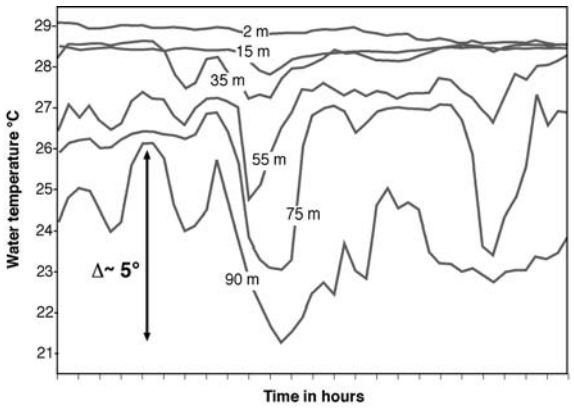

Figure 3: Data from Wolanski et al. (2004) recording internal wave activity on tidal cycles on the shelf of Palau, Western Caroline Islands, annotated to show that benthic communities living at 90 m depth experience substantial temperature fluctuations.

As a consequence, subtropical/tropical mesophotic and oligophotic biotas can experience temperature ranges of several degrees on internal-wave cycles. Those same organisms are experiencing comparable or greater changes in nutrients, organic carbon, and pCO_2. For LBF and other calcifying organisms, the latter may be particularly important as higher pCO_2 in the cooler waters, when pushed into shallower depths, should result in strong saturation gradients.

Cenozoic LBF: A brief summary

The end-Cretaceous extinction event (~65 Ma) was followed by an extended carbonate depositional hiatus (e.g., Newell 1982). Surviving shallow-water benthic foraminifers with established algal symbioses (e.g., miliolids) diversified, producing new lineages. New symbiotic associations developed in other lineages, especially diatom associations with rotalid taxa (Fig. 4). By ~60 Ma, new benthic taxa with complex morphologies were appearing (Hottinger 1998) and by the early Eocene, large, complex nummulitids were prominent carbonate-sediment producers in a variety of shelf and ramp environments (Beavington-Penney & Racey 2004). Extinctions eliminated the largest and most prominent forms of nummulitids and orthophragminids by the end of the Eocene.

New taxa arose in the Oligocene, the most prominently the lepidocyclinids and miogypsinids, though diversities, both horizontal and vertical were somewhat lower than during the Eocene apex (Beavington-Penney & Racey 2004). Lepidocyclinids and other characteristic Oligo-Miocene taxa were gone by the Early Pliocene. The amphisteginids, which arose in the Paleocene-Eocene, have since been represented through the Cenozoic, as have the Soritidae, Peneroplidae and new lineages of the Nummulitidae. With the Neogene closure of the circumtropical seaway and the isolation of Atlantic biotas, the archaiasine lineage of the Soritidae diversified in the Western Atlantic, while the Calcarinidae diversified in the Indo-west Pacific.

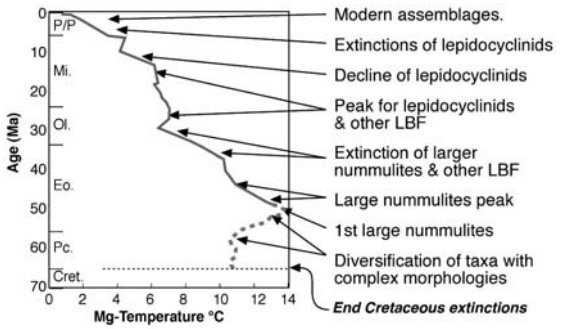

Figure 4: Comparison of the development of deep-sea temperatures (Leer et al. 2000) with diversification and extinction history of larger benthic foraminiferal (LBF) lineages (Hottinger 1998).

Given the prevalence of LBF as carbonate-sediment producers during the Cenozoic, especially during the Paleocene-Eocene, understanding and interpreting the environments in which LBF were living continues to be both scientifically and economically important. Hallock et al. (1991) compared Paleogene evolution and extinction events in LBF and planktic foraminifers, postulating that changing patterns in ocean circulation influenced nutrient regimes that were reflected in changing biotic assemblages. One goal of our paper is to consider how the evolution of oceanic conditions during the transition from the Greenhouse world of the early Paleogene to the Icehouse world of the Neogene influenced mesophotic to oligophotic habitats and biotas.

An interesting comparison can be made between the history of the LBF as interpreted by Hottinger (1998) and history of ocean stratification, as indicated by bathymetric temperature gradients that have been reconstructed for the subtropical north Pacific (Dutton et al. 2005). Note that the diversification of the large nummulites and other Paleogene LBF occurred when the deep sea was warmer (Fig. 4). The apex of these groups occurred when there was minimal temperature gradient between the thermocline and the deep sea, as reflected by minimal differences between $\Delta^{18}O$ in the shells of surface-dwelling planktic foraminifers and the shells of either *Subbotina*, which are thermocline-dwelling foraminifers, or shells of deep-sea benthic foraminifers (Fig. 5). In contrast, times when bottom temperatures were rapidly decreasing were characterized by increasing rates of extinctions of LBF (Fig. 4).

Directions for future studies

We postulate that the history of changes in Cenozoic ocean circulation associated with changes from early Paleogene Greenhouse to Neogene Icehouse conditions are recorded in evolutionary changes in LBF biotas. We recommend that future studies compare details of stratification of the ocean, as recorded by planktic foraminifers, with corresponding changes in LBF assemblages. We postulate that environmental conditions of middle and outer shelves can be more thoroughly interpreted by understanding changes in thermocline structure of impinging oceanic waters. Such progress will require more detailed comparisons of planktic and LBF records, and more research on the role of internal waves on modern outer shelf habitats.

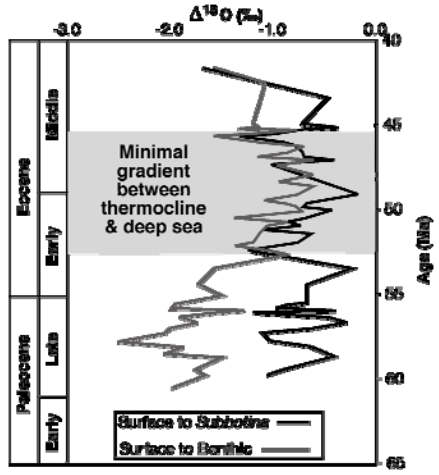

Figure 5: Data from Dutton et al. (2005) showing surface-to-thermocline (*Subbotina*) versus surface-to-bottom $\Delta^{18}O$ gradients, which indicate temperature gradients at the Shatzky Rise, subtropical North Pacific, during the Paleocene and Eocene. The bracketed time when differences between the gradients were minimal corresponds to the apex time for Eocene nummulites and other LBF according to Hottinger (1998).

Abstract. The Cañada Honda (CH) fossil coral reef, located in SW Dominican Republic, provides a unique opportunity to examine reef accretion in a high-sedimentation environment between 9.0-5.0 ky ago. Annual linear extension of fossil corals was determined for comparison with data from modern coral reefs. The reef is characterized by the high abundance of sediment-tolerant coral species, their tendency to form almost monospecific stands and grow as domes-cones with ragged margins. Also, colonies of *Montastraea faveolata* commonly contain bands of sediment incorporated within their skeletons. Calibrated radiocarbon ages of fossil corals range from 9,256±137 to 6,737±94.5 BP. Correlation with Holocene sea-level curves indicates that most corals on CH developed at depths greater than 15m. Growth rates varied from 0.09-0.44 cm/yr and suggest reduced light penetration caused by coral growth at such depths. Reef sediment is characterized by more than 85% carbonate material. A significant portion of the carbonate is allochtonous and was derived from nearby Neogene limestones. The reef was able to survive under these conditions because of the high carbonate content of incoming terrigenous sediment and that storms probably occurred sporadically providing intervening low-sedimentation periods during which reef corals could respond and grow back, "keeping-up" with sedimentation.

Key words: Holocene, siltation, linear extension, Caribbean

Introduction

Measurements of coral growth rates (as vertical extension) are used regularly as reef health indicators particularly in environments characterized by high terrigenous sediment input (e.g. Cortés and Risk 1985). Turbidity associated with suspended sediment and enhanced phytoplankton productivity reduces light penetration and the photosynthetic yield in corals (Cortés and Risk 1985; Philipp and Fabricius 2003) while the removal of settled particles from the coral increases metabolic costs (Telesnicki and Goldberg 1995; Fabricius 2005). As a result, a decrease in the annual growth rates of corals is expected.

For the past three decades a decline in reef coral abundance and diversity is being observed globally (Hughes 1994; Ginsburg 1994; Aronson et al. 2002) due to anthropogenic and natural causes. Increased coastal development and agriculture runoff leading to higher sediment accumulation and resuspension, together with discharge of sewage and industrial waste into the ocean have been blamed as major causes for modern coral reef decline (Hughes 1994; Hughes and Connell 1999; Morelock et al. 2001). A major question exists in terms of the relative roles that anthropogenic and natural disturbances play in the current trend of reef decline. The majority of the studies concerning reef health, siltation stress and low coral growth rates come from modern reef sites, many of them affected to a great extent by anthropogenic disturbance (e.g. Cortés and Risk 1985; Scoffin 1986; Edinger et al. 1998, 2000). Therefore it can be very difficult to differentiate the individual effects of natural versus anthropogenic disturbance. Some studies on coral reefs with natural high sediment input and resuspension show noteworthy differences compared with those with significant anthropogenic disturbance (Larcombe et al. 2001).

A reasonable way to differentiate anthropogenic disturbance versus natural disturbance is to study records of well-preserved fossil reefs in detail and compare the data with that gathered from modern coral reefs. This kind of approach has already been implemented in several studies (e.g. Pandolfi and Jackson 2001; Aronson et al. 1998; 2002), leading to the conclusions that current coral degradation has no precedent in the recent past. The purpose of this paper is to present data on fossil coral growth rates from the

Mid-Holocene Cañada Honda (CH) fossil coral reef of southwestern Dominican Republic (Fig. 1). The data presented is part of a larger study in which the main interest is to elucidate the pattern of reef development within natural conditions of high sedimentation and make comparisons with information gathered in modern reef environments under similar conditions. The CH fossil reef provides exceptional advantages that make it suitable for this kind of study. It displays remarkably well-preserved subaerial exposures of shallow-water reef environments dated between 10,000 to 4,500 years ago (Taylor et al. 1985). The young age (Mid Holocene) and the relatively dry climate has resulted in excellent preservation of original aragonitic skeletal mineralogy of fossil corals (Greer 2001). The CH fossil reef thrived in a high sediment environment as pointed out by Mann et al. (1984), Taylor et al. (1985) and Stemann and Johnson (1992) providing a unique opportunity for comparing a reef that developed under conditions of natural stress and disturbance with modern reefs that have been subjected to varying degrees of anthropogenic stress.

Material and Methods

Field data collection

Variations in the sedimentary environments as well as coral assemblages were studied using quadrats along 18 vertical transects (Fig. 2) for a total of 67 quadrats. Information such as presence, abundance, morphology and distribution of corals were determined as well as the presence of other important taxa such as gastropods, serpulids, oysters and echinoderms. The importance or presence of reef sediment within the quadrat was also measured. Quadrats were placed on vertical exposures and each of the 100 points was counted as sediment or fossil. Locations for vertical transects were randomly selected and an effort was made not to bias placement on especially large or well preserved colonies.

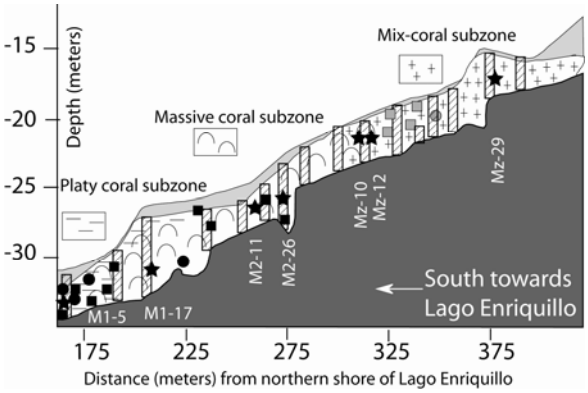

Figure 2: Cross-section of the Cañada Honda fossil reef showing location of transects (bars) and corals sampled for growth rate analyses. Squares represent *M. faveolata* samples and circles represent *S. siderea* samples. Difference in color denotes different subzones. Star represents samples for radiocarbon dates. *Acropora cervicornis* zone not shown.

Coral Growth Rates

Growth rate analyses focused on the corals *Montastraea faveolata* and *Siderastrea siderea* which are the two most abundant massive coral species in the CH fossil reef and additional growth rate data are available for each (e.g. Cortés and Risk 1985; Gischler and Oshmann 2005). Samples were collected randomly, identified and all the pertinent field information (photography, elevation, location in the reef) recorded (Fig. 2). To determine growth rates, corals were cut into 3-5 mm wide slices. The central slab of the colony, where the maximum growth occurs, was then polished and X-radiographed to reveal skeletal growth patterns. The radiographs were then scanned and the high and low density growth bands revealed by X-rays were measured using Coral XDS v. 3.0 (Coral X-radiograph Densitometry System) software that detects and measures changes in image density.

Radiocarbon dates

Seven of the coral specimens analyzed for growth rates were chosen for radiocarbon dating. The samples were selected according to their location on the CH reef in order to obtain coral ages at different elevations throughout the outcrop. In conjunction with well established Holocene sea-level curves (e.g., Toscano and Macintyre, 2003), radiocarbon ages were used to constrain paleodepths of the corals at their time of growth as well as determine the pattern of reef accretion through time. Radiocarbon analyses were conducted at the National Ocean Sciences AMS Facility of the Woods Hole Oceanographic Institution

in Massachusetts, USA. Radiocarbon ages obtained from the AMS facility were then calibrated to account for the ^{14}C local marine reservoir. Calibration was done using the CALIB software v. 5.1.

Sediment sampling and analyses

Nineteen sediment samples from the CH fossil reef were analyzed for this study. In addition, four sediment samples from a fluvio-deltaic sequence overlying the Mid-Holocene fossil coral reef from Las Clavellinas (Fig. 1) were analyzed for the purpose of determining composition of allochtonous terrigenous sediment that reached the former Enriquillo Bay. Analyses consisted of determination of the relative organic and carbonate content. A portion of each sample was weighed and then Clorox was added to remove organic matter. Samples were washed with distilled water, dried in an oven at 100˚C and weighed again to determine the percent of organic matter removed by the Clorox. This process was repeated again with a solution of 10% Hydrochloric Acid (HCl) to remove the $CaCO_3$ of the samples.

Results

Community structure

Twenty-two Scleractinian coral species were identified in the CH fossil reef (Table 1). The most abundant coral species is the massive coral *Siderastrea siderea* with approximately 47.4% of the coral counts followed by *Montastraea faveolata* (8.73%), *Undaria (Agaricia) agaricites* (7.66%), *Colpophyllia natans* (5.83%), *Montrastraea franksi* (4.13%), and *Acropora cervicornis* (3.86%). In general, the CH fossil reef can be divided into two major zones. The first, a branching or *Acropora cervicornis* zone which dominates throughout the upper reef (~0 to -15 m elev.). In this zone, the coral species *Acropora cervicornis* has an abundance of 37.9% followed by *Montastraea annularis* and *Undaria (Agaricia) tenuifolia*. The second zone or *Siderastrea siderea* zone consists mostly of massive corals where the coral species *Siderastrea siderea* range from 50% to 70% and can be divided into the following three subzones in descending elevation order (-15 to -35 m elev.); a high diversity assemblage or mix-coral subzone, a low diversity assemblage or massive coral subzone and a platy coral subzone (Fig. 2). A similar pattern of coral species distribution was obtained by Stemann and Johnson (1992).

Coral morphologies were grouped into five categories. These are platy, hemispherical, conical, columnar, and branching (Table 2). The dominant morphology in the CH fossil reef is hemispherical (34.9%), followed by conical (20.5%), branching (16.8%), platy (16.4%) and columnar(11.4%). Most of these morphologies are associated with reduced light penetration and turbidity caused by high sedimentation (James and Bourque 1992; Van Woesik and Done 1997). In addition, 51% of the counts from the massive coral morphologies (i.e. hemispheres, columns and cones) have ragged margins (Table 2) which is indicative of sedimentation rates equal or almost equal to the coral growth rates (James and Bourque 1992).

Coral Growth Rates

Twenty-five coral colonies were analyzed to determine annual growth rate. For the massive coral *Montastraea faveolata*, annual growth rates ranged from 0.09 to 0.44 cm/yr (Table 3). In coral colonies of *Siderastrea siderea*, annual growth rate varied from 0.2 to 0.4 cm/yr. Compared with *Montastraea faveolata*, *Siderastrea siderea* showed less variability in the annual growth rate values (Table 3).

Table 1. Distribution (% counts) of coral species and sediment in Cañada Honda

Coral species	C. Honda
Siderastrea siderea	47.38
Montastraea faveolata	8.73

Platy	16.4	-	16.4
Cones	10.5	10.0	20.5
Columns	8.6	2.8	11.4
Domes	13.7	21.2	34.9

Radiocarbon ages

Calibrated radiocarbon ages obtained from the seven CH coral samples ranged from 9,256.0±137 BP to

6,736.5±94.5 BP (Table 4). The oldest age is from a specimen of *Montastraea faveolata* (9,256.0±137 BP) followed by a specimen of *Siderastrea siderea* (8,628.0±165 BP). The youngest age was found in a specimen of *Montastraea faveolata* (6,736.5±94.5 BP) followed by a specimen of *Siderastrea siderea* (7,465.0±83 BP). Correlation of radiocarbon ages with a well-established Holocene sea-level curve (i.e. Toscano and Macintyre, 2003) helps establish the approximate paleodepth at which coral specimens grew. Except for coral sample Mz-29, which occurred in a topographic high (Fig. 2), the remaining corals developed at paleodepths of no less than 15m (Table 4).

Sediment composition

Sediment composition analyses conducted on the nineteen sediment samples from the CH fossil reef are characterized by a high percentage of carbonate (i.e. $CaCO_3$) material (Table 5). Carbonate content varied from 84% to 96%. In contrast, the sediment samples from the fluvio-deltaic deposits in Las Clavellinas are characterized by carbonate content varying from 41% to 69% (Table 5).

Discussion and Conclusions

The Mid-Holocene Cañada Honda fossil reef in the Dominican Republic shows signs of development in an environment of high sedimentation based on the relatively high abundance of sediment-tolerant coral species, the tendency of these to form almost monospecific stands, and the propensity of individual colonies to grow as encrusting, dome-shaped, platy-like forms. Also the finding of sediment incorporated into coral skeletons supports the idea of siltation stress during the accretion of the reef.

Coral growth rates measured for fossil *Montastraea faveolata* in CH are relatively low compared with growth rates of modern corals from sites throughout the Caribbean. These low growth rates resulted from low light penetration most likely from growth at 15m or more (Table 4). Nonetheless, if these conditions are correct, coral development occurred at depths not expected for a reef under siltation stress. However, the high carbonate content of the incoming terrigenous sediment allowed greater light penetration than similar amounts of siliciclastic sediment, and,

S-400-1	2	95	3

thus, allowed corals to grow at greater depths than typically expected under these conditions. Other possibilities are that even though sedimentation was high, it occurred sporadically allowing time for the reef corals to respond and grow back, in such a way that they were able to "keep-up" with sedimentation and sea-level rise.

The coral growth rates measured for *Siderastrea siderea* in CH are similar to growth rates of this coral from other sites in the Caribbean including sites in shallow water, with siltation stress and great depths. Also, *S. siderea* colonies from CH did not show clear bands of incorporated sediment into the skeleton compared with those of *Montastraea faveolata*. This fact highlights the ability of this coral to reject sediment and survive in stressful environments. Therefore, coral growth rates of *Siderastrea siderea* should not be taken as an unequivocal indicator of turbidity or other signs of reduced light penetration until more is known about the feeding mechanism, metabolism and skeletogenesis of this coral species.

Results of long-term bioerosion study: Belize patch reefs

H. Lescinsky, M. Hill, B.A. Hoedt

Otterbein College, Westerville Ohio 43081, United States

Abstract. Bioerosion rates were tracked for up to 8 years on patch reefs in central Belize using natural and experimental substrates. Mortality from bleaching in 1998 provided the start of a natural experiment in which *Acropora cervicornis* and *Agaricia tenuifolia* were collected at 1-2 year intervals for 8 years. In addition, experimental substrates (conch shells) deployed along a depth gradient (1-12m) were retrieved at 1, 3, and 5 year intervals. Macroboring bioerosion rates were initially highly linear (5-6%/yr), and inversely related to depth. After 3-4 years macroboring bioerosion slowed and average maximum intensity tended toward approximately 40%. Individual substrates had a threshold of around 50% which may reflect the maximum gallery density for *Cliona* or the collapse and disappearance of more highly bored substrates. Wide spread coralline algae encrustation and the persistence of corallite surface texture suggests that external bioerosion from grazing was negligible. These results differ from previous studies that have found grazing bioerosion to be an order of magnitude or more greater than macroboring. This study highlights the greater importance of boring than grazing in several Caribbean reef habitats and the need to re-evaluate the relative impacts of inside-out vs outside-in bioerosion on coral reefs.

Key words: Belize, Bioerosion, Bleaching, Boring, Grazing

Introduction

In order to understand coral reef accretion, it is important to keep in mind that to a first approximation most biological coral growth is ultimately lost from the reef structure via bioerosion and transport (Glynn 1997). This is evident on apparently healthy reefs that have little accretion over geologic time (Smithers et al. 2006), in reef cores where fast growing corals do not result in faster reef accretion than slower growing corals (Gischler 2008), and in nutrient rich areas where bioerosion predominates over fast coral growth (Edinger et al. 2000).

Despite the importance of bioerosion to reef formation, there are few quantitative studies of bioerosion, especially in the Caribbean. Studies on bioerosion rates in the Pacific and Indian Oceans suggest that in most cases external bioerosion from scraping herbivores such as parrotfish and sea urchins far exceeds internal bioerosion by macroborers such as sponges and bivalves generally by more than an order of magnitude (Table 1).

The emerging outside-in, rather than inside-out paradigm for reef bioerosion is an important consideration for geologists who focus primarily on macroboring and microboring rather than grazing bioerosion (e.g., Perry and Hepburn 2008), and only recently have attempts been made to reconstruct grazing in the rock record (Lescinsky 2008).

The outside-in paradigm for reef bioerosion, however, is derived from studies that used sawed blocks of *Porites* that were bolted to the reef (Kiene and Hutchings 1994; Chazottes et al. 2002; Osorno et al. 2005). Results from these studies may be most applicable to flat, exposed reef-rock surfaces and they may be less applicable to other types of reef substrate and environments. Previously reported low macroboring rates are also at apparent odds with studies on experimental substrates (Neumann 1966, Schonberg and Wilkinson 2001) and naturally bleached corals (Sheppard et al. 2002; Schuhmacher et al. 2005) that document rapid sponge bioerosion. The grazing paradigm also does not hold for all reefs. Boring outpaced grazing at nearshore sites on the Great Barrier Reef (Table 1), and on the Belize patch reefs reported here.

Methods

Natural Experiment

Coral bleaching in 1998 killed healthy *Acropora cervicornis* and *Agaricia tenuifolia* stands on Wee Wee Cay (16.620 N x 88.090W) and Peter Douglas Cay (16.700 N x 88.170W) in southern Belize approximately nine miles off the east coast of the mainland in the Stann Creek District (Aronson et al. 2000, Paul Shave, pers. com.). Beginning two years after bleaching, coral pieces were haphazardly collected on snorkel from dead stands

along the north ridge of each cay. Collections were made after 2, 3, 4, 6, and 8 years (November or December of 2000, 2001, 2002, 2004, 2006). *Agaricia* patches were located just below the lip of the windward rise (3-4m) while *Acropora* dominated on the ridge tops (2-3m). Corals stands were obvious at the beginning of the study with many long (>20cm) pieces of *Acropora* and in-place *Agaricia* with many blades. By the end of the study, the colonies were largely obscured, especially because of coral resurgence on Wee Wee Cay beginning in 2006. Coral pieces retrieved at the end were smaller and many were detached rubble.

Experimental deployments: Conchs

Conch shells (*Strombus gigas*) harvested live for food and without macroboring were deployed along a depth gradient at 1.5m, 6m and 12m along the north face of Wee Wee patch reef (approximately 100 yards west of Wee Wee Cay). Only shells with a mature flared lip, and without encrustation (or with minor encrustation removed) were used. The 12m site was near the base of the slope above a flat plain of carbonate mud. Some shells were partially buried by fine sediment during the course of the study. Thirty or more shells were deployed at each of the three depth stations to allow collection of 10 shells each after 1 year (2002), 3 years (2004) and 5 years (2006). Shells were then sawed to remove the center section of the mature apertural lip for analysis.

Bioerosion Analysis

For corals, 20 pieces per sample (80 total: 2 species at 2 sites), per time interval were sectioned using a rock saw. For conch lips, 10 pieces per sample (30 total, 10 at 3 depths), per time interval were sectioned. Each piece was cut into three sections which were analyzed for bioerosion. Each section was digitally photographed and overlaid by a grid of points. Bioerosion proportion was determined by the number of points located over borings divided by the total points (>100). Microboring was not examined in this study.

Table 1: Results of studies that calculated both internal and external bioerosion. External generally exceeds internal bioerosion by an order of magnitude except in nearshore Great Barrier Reef (GBR) settings.

Results

Natural Experiment

Over the eight years of study, dead branching colonies of *Acropora* and *Agaricia* became increasingly fragmented and in some cases overgrown, although former stands remained easy to locate and sample. Coral surfaces were often partially encrusted by coralline algae (Fig. 1). On unencrusted surfaces, original corallite topography, such as the raised polyp rims in *Acropora* was generally maintained There was little to no evidence of scrape marks from grazing bioeroders.

Macroboring was almost entirely from several ichno-taxa of boring sponge (undifferentiated in the data). Worm and bivalve borings were rarely encountered. Over the first 4 years, average macroboring bioerosion of the coral rubble proceeded at about 6%/year in a highly linear fashion (Fig. 2-3, Table 2). Rates decreased towards the end of the study. Variation between the three sections per sample and between samples was substantial but did not obscure overall trends.

Between sites there was a small but significant (ANOVA <.001) difference with Wee Wee having slightly greater total bioerosion over most of the study, even though after the first 3 years the overall rates (slopes of best fit line) were similar.

Bioerosion rates between *Agaricia* and *Acropora* were similar (6%/yr). Higher absolute "bioerosion" in *Acropora* in Fig. 3 results from the inclusion of the initial porosity of the coral skeleton. Unbored *Acropora* skeleton has initial growth pores that occupy a varying amount of the cut surface depending on the age of the branch and the angle of the cut. We used 5% initial porosity (an average of several measurements) as our initial condition (y-intercept).

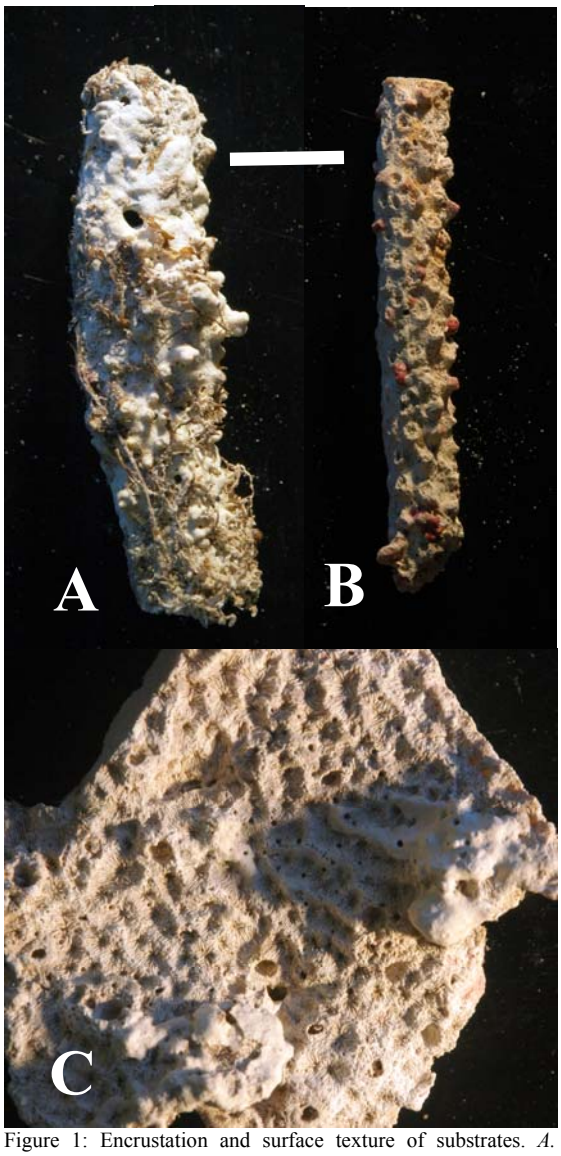

Figure 1: Encrustation and surface texture of substrates. *A. cervicornis*, 6 yrs (A) has knobby coralline algae and lacks evidence of grazing bioerosion. *A. cervicornis,* 8 yrs (B), partial retains corallite collars with limited encrustation by *Homotrema rubrum*. *A. tenuifolia*, 6 yrs (C), preserves original corallite topography. Scale bar is 1 cm.

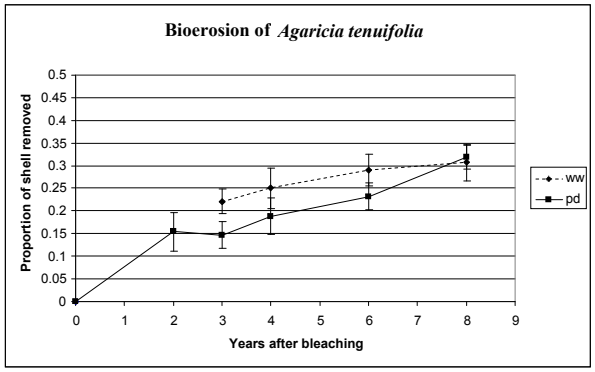

Figure 2: Bioerosion over 8 years for *Agaricia tenuifolia* killed in the 1998 bleaching. Mean values and 95% confidence intervals for Wee Wee Cay (ww) and Peter Douglas Cay (pd). Bioerosion has a nearly constant rate over the first 4 years of 5-6%/year. .

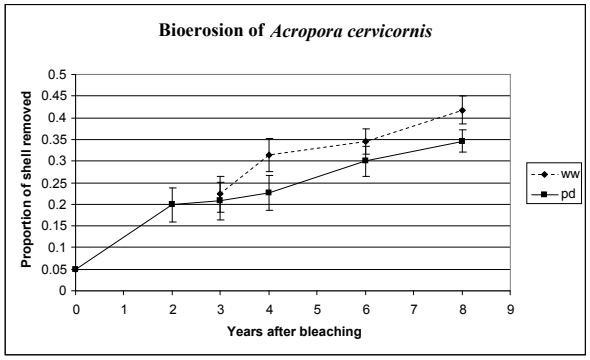

Figure 3: Bioerosion over 8 years for *Acropora cervicornis* killed in the 1998 bleaching. Mean values and 95% confidence intervals for Wee Wee Cay (ww) and Peter Douglas Cay (pd). *Acropora cervicornis* has a living porosity of 5-10% (depending on age, angle of cut); 5% is used here for the y-intercept.

Experimental Substrates

For the first 3 years, experimental conch shells were macro-bored at around 9%/yr at the two shallower depths, a rate higher than those of natural substrates at similar depth. There was no significant difference between bioerosion at the two shallower stations, but the deepest station (12m), bioerosion decreased to about a half (4.4%/yr).

Table 2: Bioerosion rates (proportion of skeleton removed per year) as measured as the slope of best fit line of the average of both sites. R^2 values for linear regression lines are high over 3+ years suggesting a tight correlation between time and macroboring intensity.

	Bioerosion Rate:	**R^2: 3 yrs**	**R^2: 4 yrs**
Agaricia	.063	.97	.95
Acropora	.058	.94	.96
Strombus (1.5m)	.096	.999	
Strombus (6m)	.092	.97	
Strombus (12m)	.044	.996	

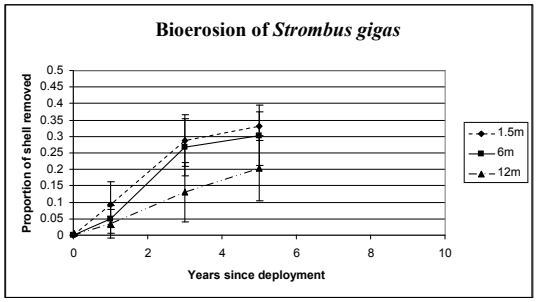

Figure 4: Bioerosion over 5 yeas for experimentally deployed *Strombus gigas* shells. Over the first 3 years the bioerosion rate is linear at about 9%/yr for <6m and 4.4%/yr for 12m sample. Mean values with 95% confidence intervals.

Discussion

Direct comparisons of the rates reported here (6-9%/yr in shallow water) with those from previous studies are difficult because bioerosion rates are generally reported as a function of weight loss per reef surface area (kg m^2yr^{-1}). This metric is easily applied to small flat experimental plates but is more difficult to apply to complex 3-D substrates or where the vertical extent of boring is not known.

In this study, bioerosion of 6% yr^{-1} at a density of about 1 g/cm^3 (Boucher et al. 1998) corresponds to a weight loss of 60kg m^2 yr^{-1} for a 1m cube and .6kg m^2 yr^{-1} for a $1m^2$ slab 1cm thick. To correct for surface area of the coral we can divide this number in half for tabular colonies with erosion on two sides (ex. *Agaricia*, *Strombus* shell) or for cylindrical colonies (e.g., *A. cervicornis*) a number depending on diameter (1cm: .25, 2cm: .5, 4cm: 1). To relate colony surface area to reef planar area, an additional multiplication factor would be needed since the former may be many times the latter.

Given the assumptions inherent in the conversion, we suggest that 6% yr^{-1} translates to around .3 kg m^2 yr^{-1}, and rates 4-5x greater are appropriate if related to planar reef surface. Within this range of rates, macroboring bioerosion on the Belize shelf is considerably higher than reported in most previous studies (Table 1), except where living sponges were attached directly to substrates (e.g., Neumann 1966, Rutzler 1975).

An important conclusion of the study is that bioerosion rates were surprisingly linear and similar between sites and substrate types (Fig. 5). For example, after 3-4 years, best fit lines had R^2 values .95 or greater for all three substrate types (*Agaricia*, *Acropora,* and *Strombus*). There was no time lag in the onset of macroboring has been suggested in some previous studies (Bromley et al. 1990).

Using linear bioerosion rates as a tool for estimating removal time for dead corals, or as a proxy for post-mortem exposure requires two important caveats. The first is that an upper limit to macroboring probably exists. Boring sponges have characteristic gallery patterns and may switch to lateral extension after excavating about 50% of the substrate (Rutzler 1975). Bored substrates also become increasingly fragile and will eventually collapse into smaller pieces that would be omitted from collections. For example after 5 years, several conch shells were missing parts and collapsed during retrieval.

A second consideration is that bioerosion is greatly slowed by burial. On reefs, vast differences in bioerosion and other taphonomic metrics occur between substrates resting on the seafloor, and those located above it on racks (Lescinsky et al. 2002). Intervals of burial and excavation may mix substrates of very different ages. For example, mollusc shells of similar preservation may be hundreds of years different in age in some settings (Meldahl et al. 1997).

The results of this study also call for a re-evaluation of the outside-in paradigm for reef bioerosion. Although previous studies (Table 1) have found grazing to be an order of magnitude greater than macroboring this is not the case for branching corals on Belize patch reefs. Grazing rates, although not measured directly are apparently minimal because coral surface texture is retained and there are thick coatings of coralline algae. In addition, if outside-in bioerosion rates were comparable to macroboring, our small substrates, would have disappeared entirely over the course of the study.

It is likely that we grazing bioerosion dominates macroboring bioerosion in many reef settings worldwide, though our results may also reflect in-part low grazing bioerosion in the Caribbean. As pointed out by Bellwood and Choat (1990) the Pacific has a diverse complement of excavating parrotfish but in the Atlantic *Scarus* species are all functional scrapers and only *Sparisoma viride* (stoplight parrotfish) is a significant bioeroder. In addition, bite size and bioerosion are related to fish size, and *S. viride* is dwarfed in size by the most important bioeroders in the Pacific, such as *Bolbometopon* which accounts for 88% of the bioerosion on outer reefs (Hoey and Bellwood 2008). Regional die-off of *Diadema* sea urchins would also lower grazing bioerosion in the Atlantic. Overfishing on the Belize reefs is probably not a direct cause because *S. viride* is abundant there (Rotjan and Lewis 2006, Brown-Saracino et al. 2007).

While regional processes may contribute to the differences described here, differences in methods were also likely important. The substrates in this study were small plates and branches of colonies that have numerous cryptic surfaces that would be difficult for large parrotfish to feed on. Similarly, invertebrate grazers such as sea-urchins may stay primarily on reef-rock and avoid branching corals and rubble (e.g., Bak

1990). Bioerosion of branching corals and corals with complex colony form, therefore, probably proceeds very differently than bioerosion of massive corals. When viewed from the perspective of the whole-reef, this is very important since branching corals are fast growing, dominate many shallow reef zones, and comprise most reef rubble. Macroboring probably also dominates in reef zones with low grazing, such as deeper water (Fox and Bellwood 2007), and throughout the reef in crypts which may comprise as much as 75% of the reef surface area and support diverse suspension feeding communities (Richter and Wunsch 1999).

In conclusion, bioerosion on the patch reefs of Belize occurs primarily through macroboring rather than grazing. This may in part result from differences of grazing bioeroders in the Caribbean, but it is also probable that inside-out bioerosion is a dominate force on most reefs in many zones. With the exception of large dead coral heads and smooth reef rock, boring may dominate in other situations such as where branching coral and rubble are abundant and in deeper water and crypts where grazing is greatly diminished.

Reef slope failure in the northeastern corner of Malè, Maldives

M. Riyaz[1], K.H. Park[1]

1) Asian Institute of Technology School of Engineering & Technology, P.O. Box 4, Klong Luang, Pathumthani 12120, Thailand.

Abstract. This study examines reef-slope failure that occurred on the northeastern corner of Malè Island on the 6th of February, 2002. Malè, the capital of the Maldives, has an area of 1.5 m^2 and a population of 130,000. The failed slope area was mapped and systematically investigated by comparing aerial photographs and satellite images from 1969 to 2007. The investigation shows that the reef-flat caprock consists of 2 to 3 m of slightly cemented coral and rubble overlying 4 to 6 m of weakly cemented, highly erodible coral sand and rubble located 10 to 30 m down the 30° slope. The failure may have occurred as a single event during which an integral rock mass disintegrated into individual blocks. Radiocarbon dating of the rock samples indicates rapid vertical reef growth, but horizontal progression played a more important role in reef formation. Aerial photographs and satellite images show four additional reef-failure areas on the northern side concentrated in areas of heavy urban-development overburden and continuous vibration from industrial activities. Due to reef failure, the strongly cemented caprock was removed, and the weakly cemented highly erodible layer was exposed to further erosion. The eroded parts are expected to fall into the atoll lagoon and cause further retreat of the reef edge. Proper remedial action must be taken to maintain overall stability and ground-bearing capacity of the island.

Keywords: Reef; slope failure; Malè; Maldives

Introduction

Malè is the capital city of the Maldives with an area of 1.5 m^2 and a population of 130,000 people. The island, located within and along the south eastern edge of a large north/south-trending atoll, has been reclaimed to the maximum extent possible, and heavy tetra-pod breakwaters have been constructed on the reef flat around the island. Heavy weight from new constructions, buildings, and industrial activity burdens the reclaimed area (Fig. 1).

Submarine reef slope failure triggered 19 days after a barge collision incident with an existing solid jetty that had been built on the reef flat in the northeastern corner of Malè in 1999. Two years after jetty completion and onset of industrial construction, the slope in that area failed in February 2002. Blocks of reef flat fell into the atoll lagoon, creating a number of new cracks that developed in various parts of the reef flat and slope. Some of these cracks extend 20 to 30 m into the slope.

Generally, slope failure was initiated by stress construction at the edge of the slope and was followed by cracking. Major factors that govern slope stability are slope angle and material properties, such as cohesion and the angle of friction. Typically, slopes with an angle of 20 to 30° and low cohesion are vulnerable to failure. In this case, however, the slope angle was around 10 to 15° and the material consisted of very cohesive and strongly consolidated 1- to 2-m thick reefal limestone. Thus, it is suspected that slope failure was affected by stresses induced by the excessive weight put on the island subsurface.

Study Methods

Investigation and systematic monitoring of collapsed reef area on the northeastern corner of Malè has been ongoing since 2004. The geologic structure of the collapsed area was mapped and systematically classified following general procedures in geotechnical engineering.

Cubes of collapsed blocks were measured and depths were recorded along three profiles that emanate from the edge of the reef flat and follow the reef slope onto the atoll lagoon floor to a depth of 45 to 50 m. The intra-reef structure was observed at the collapse scarp from the reef surface to –35 m. Rock samples collected from various depths of the collapsed area were dated using the radiocarbon method. To monitor the progress of cracks in the collapsed area, two pegs were installed on both sides of the crack and tightly connected with fishing lines. Aerial photographs and satellite images of Malè reef were taken in 2007 and were compared with the previous images taken in 1969, 1996, and 1999.

Results and Discussion

The reef-flat caprock consists of 2- to 3-m-thick slightly cemented coral rock and rubble. Beneath the caprock is a 4- to 6-m-thick weakly cemented highly erodible mixture of coral sand and coral rubble. Farther down (10-30 m), the 30° slope has been built up by loose gravel and sand.

Figure 1: A Digital Globe® satellite image of Malè taken in 2007, top, aerial photograph of north eastern corner of Malè taken in 1999 at the bottom, showing the solid jetty prior to the collapse.

The block field lies on the atoll lagoon floor at a depth of 30 to 40 m. The failure might have occurred as a single event, and as the rock mass was in motion, the mass disintegrated into individual blocks to form the block field. Total volume of the rockslide is estimated to be several thousand cubic meters (Figs. 2 & 3).

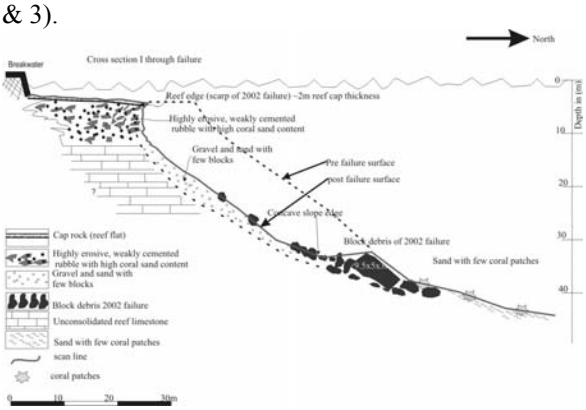

Figure 2: Cross section of failure area.

The monitoring pegs installed in 2004 have been broken. In addition, new cracks to the east of the collapsed area were observed in 2007. The cracked blocks appear to be unstable and continuously and slowly moving (ERC 2007).

Both the eastern and western scarps as well as the collapsed part of the reef are exposed to strong currents and wave action. Thus, the weak layer in the reef is continuously being eroded and is undercutting the reef edge. A freshly fallen reef block was found during the survey.

The collapsed scarp shows that the reef surface is consolidated at the top 2 to 3 m by the accretion of tabular, massive, and stubby branching corals. The sedimentary structure changes gradually to the coral casts near the bottom of the scarp (Fig. 4).

Radiocarbon dating of rock samples shows the oldest material occurs at the 20-m depth, and the youngest is at the top of the reef. This indicates that, even with the rapid growth of the vertical reef section, the horizontal progression of the reef played a more vital role in reef formation.

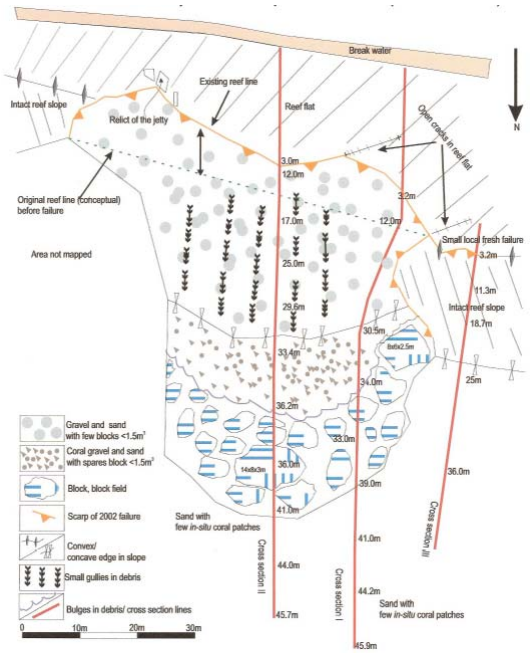

Figure 3: Plan view of failure area.

The reef surrounding Malè Island is continuous, and no collapsed area is found in aerial photographs taken in 1969 (Fig. 5). The reef area of the northeastern corner had not failed, whereas the area on the northwestern part had failed. Furthermore, satellite images taken in 2007 showed failure at four circled areas (Fig. 6). Those failures are concentrated in the areas of heavy construction and continuous industrial vibration. Although these areas are clearly visible in the photos, they need to be validated through field observations.

The study found that the geomechanical cause of the slide is a combined weakly cemented layer of coral sand and rubble several meters thick and urban construction. Similar subsurface conditions were determined by core drilling at Rasdhoo atoll (Gischler et al. 2008).

It is evident that the reef scarp, including the weak layer, is exposed to prevailing current and wave action and hence to active scouring beneath the consolidated layer. It is expected that parts of the reef will continue to fall into the atoll lagoon, leading to additional backward retreat of the reef edge toward the breakwater.

Further investigation is required to determine the lateral extent of the weak layer. Such an investigation is crucial prior to taking any remedial measure to stabilize the unstable reef slope. Further analysis of slope stability is also needed (Damjanac 1999).

Abstract. Beach nourishment in Southeast Florida involves dredging sand source borrow areas located between offshore reefs. From May 2005 to February 2006 Broward County, FL. nourished 10.9 km of beach with 1.5 $\times 10^6$ m^3 of sand. As part of a program to monitor potential reef community impacts, a visual stress index was developed from laboratory experiments and histological analyses for three stony coral species (*Montastrea cavernosa*, *Solenastrea bournoni*, and *Siderastrea siderea*). Scoring involved healthy = 0; moderately stressed = 1 (polyp swelling, increased mucus); markedly stressed = 2 (coloration changes, increased mucus secretion, tissue thinning); and severely stressed = 3 (severe swelling/thinning tissue erosion/necrosis). Colonies were scored weekly at sites adjacent to borrow areas and control sites pre-, during, and post-dredging. Permit conditions were established which would suspend dredging based on mean stress index values above 1.5 at 50% of monitored sites adjacent to borrow areas. This condition was never met. However, three hurricanes, passing the region during dredging, contributed to an elevated mean stress level above 1.0. Post-dredging observations documented recovery to pre-dredging stress levels. This program was effectively used to monitor stress on a sensitive marine habitat adjacent to sediment dredging activities.

Key words: Coral stress, dredging, beach nourishment.

Introduction

Beach nourishment in Southeast Florida is commonly accomplished by dredging from sand deposits located between offshore coral reefs and moving the sand to shore. Broward County, Florida, USA constructed 10.9 km of beach from May, 2005 through February, 2006, utilizing a hopper-dredge and placing 1.5 million cubic meters of sand, from 5 different sand borrow areas (Figure 1), onto the beach. Dredging can cause elevated turbidity due to suspension of sediments. This can result in stressful conditions, including smothering and/or reduction of photosynthesis, for sessile reef organisms, such as stony corals. To monitor a real-time response of stony corals to a potentially increased, sediment induced, stress environment during the dredging process, an observational stress index was developed for three coral species (*Montastraea cavernosa*, *Solenastrea bournoni*, and *Siderastrea siderea*). This stress index was incorporated into State and Federal permits issued for the dredge operation and an average stress index threshold was developed to allow for cessation of dredging at specific borrow areas should the stress threshold be exceeded. Recovery to below threshold stress levels would subsequently allow dredging activity at the specific borrow area to resume.

Material and Methods

The stress index was developed in the laboratory and verified histopathologically (Vargas-Angel, et al., 2006). Average values above 1.5 (n=6) at 50% of sites surrounding a particular borrow area would trigger cessation of dredging at that borrow until average stress fell below threshold. Figure 2 shows typical observable stress responses of *Montastraea cavernosa* for each stress index level. Treatment study sites were established adjacent to each borrow area (Figure 1) and control sites established 4-5 km north (3 sites) and south (5 sites) of the dredge operating area. Six colonies among the three species were selected at each site. Sites were visited and stress observations made weekly for thirteen weeks pre-construction, weekly during construction (38 continuous weeks with two exceptions due to tropical cyclone activity, and weekly for eight weeks post-construction. Additional observations from non-project colonies were made occasionally from outside the study sites to verify that visual observations were close or identical to histological stress determined in the lab.

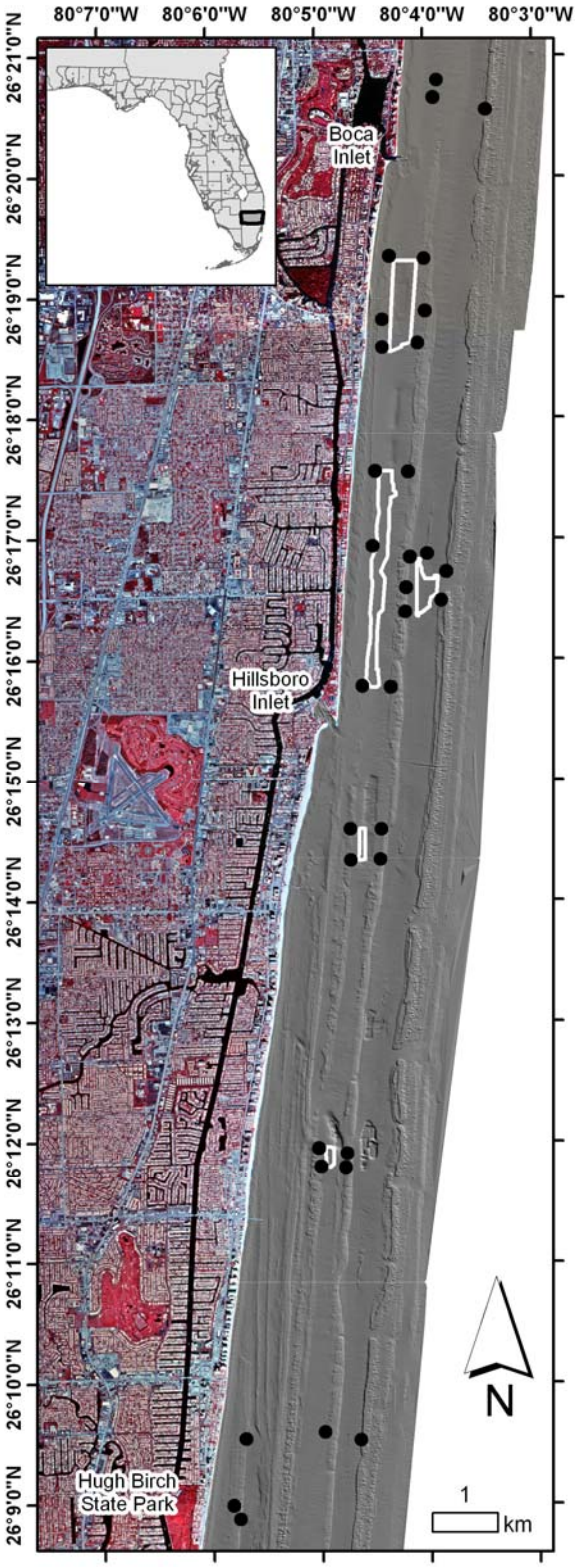

Figure 1: Map depicting sun-shaded laser bathymetry of the bottom offshore Broward County, Florida, USA. Reefs can be seen as ridges paralleling the shoreline (see Walker et al, 2008 for maps of the reefs). Dark circles are sediment monitoring sites where coral stress observations took place. Light colored boxes denote sand borrow areas between the reefs.

Figure 2a: STRESS LEVEL 0: Color appears normal; polyps are fully extended or loosely retracted; no tissue swelling; no apparent mucus sheets over colony.

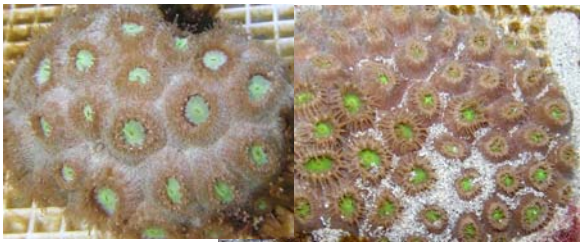

Figure 2b: STRESS LEVEL 1: Normal coloration, natural texture lines. Polyps are fully extended or loosely retracted; no apparent mucus sheets over colony; slight tissue swelling some unusual mouth opening shape and changes in the appearance of oral disk.

Figure 2c: STRESS LEVEL 2: Normal coloration to patchy bleaching. Normal texture lines begin to disappear; polyps appear "melted"; severe tissue swelling and apparent tissue thinning; presence of mucus sheets and sand accumulations between polyps.

Figure 2d: STRESS LEVEL 3: Coloration dull to brown to bleached; obvious tissue erosion and necrosis; polyps tightly retracted, deflated-looking with sunken-in oral disk areas; tissue thinning; skeleton starts to appear thru tissue. Mucus sheets present and colony shows an inability to remove sediments.

Results

Figure 3 presents photographic evidence that the observed level of stress for a *Montastraea cavernosa* colony from one of the treatment sites changed from level 0 to level 2 during construction and returned to level 1 after construction was completed. Average stress values (Figure 4) at treatment sites (n = 26 sites and 156 colonies) and control sites (n = 8 sites and 48

colonies) remained below 0.5 during the thirteen week pre-construction period and through the 14th week of dredging. The passing of Hurricane Katrina during construction week 15, Hurricane Rita during week 19, and Hurricane Wilma during week 24 contributed to immediate elevated observed average stress values between 0.5 and 1.0. Average histological stress was the highest during the summer maximum temperature (31.9^{o}) that occurred in August, 2005 (Vargas-Angel, personal communication). Average stress remained between 0.5 and 1.0 for the eight weeks of post-event analysis, indicating a recovery period to pre-impact levels longer than 8 weeks.

Figure 3a. Example of a monitored *M. cavernosa* colony at stress level 0 during construction on July 5, 2005.

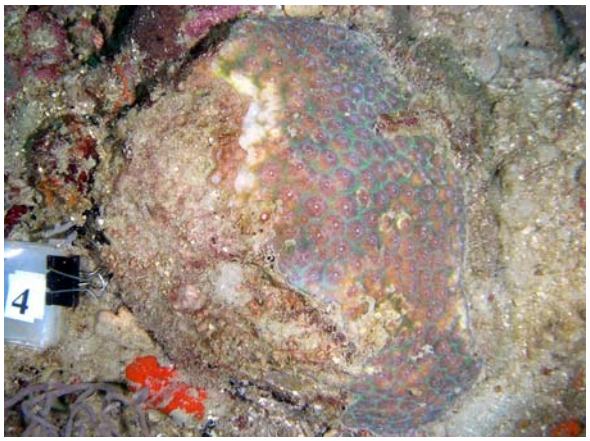

Figure 3b. The same colony at stress level 2 during construction on December 5, 2005, after the passage of three tropical cyclones.

Figure 3c. The same colony showing some tissue loss in the upper left, however, the remaining colony has recovered to stress level 1 during post construction on March 22, 2006

Discussion

Results indicate that in-situ morphological inspection and evaluation of gross changes associated with stress was an effective tool in detecting and adaptively managing impacts to corals during a dredging event adjacent to sensitive coral habitat. Due to the influence of the hurricanes during construction we can easily separate colony stress levels as a result of storms versus dredging. Average stress remained low prior to the first storm. Average stress levels only exceeded level 2 for two of six sites on two occasions at BA1. Threshold shut-down criteria were not exceeded throughout the project.

The R/V Alpha Helix Expedition: A retrospective analysis of a milestone in coral reef research

C.F. D'Elia and A.R. Harris

University of South Florida St. Petersburg and USF College of Marine Science, 140 7th Avenue South
St. Petersburg, FL 33701, USA

Abstract. The most comprehensive study of a coral reef undertaken until that time, the *Symbios Expedition*, was conducted in 1971 by an interdisciplinary team of ecologists and oceanographers. The study site was at Enewetak Atoll, Marshall Islands, and the *R/V Alpha Helix* along with shore-based facilities provided laboratory and logistical support. Many coral reef researchers are aware that this team-oriented research program made significant contributions to the understanding of coral reef metabolism and function, but the expedition itself has not been documented formally for historical purposes. Here, to assess *Symbios'* published results, we used *Citespace II*, a public domain that provides information visualization methods, bibliometrics, and data mining algorithms in an interactive visualization tool for extraction of patterns in citation data. We found that *Symbios* research results have had a significant scientific impact. Our review of historical reference materials and extensive interviews suggests some of the reasons for the expedition's success: a good science plan, strong and adaptative leadership that emphasized collaborative research, and excellent logistical support lines.

Key words: coral reef, ecosystem metabolism, nutrients, history of science, citation analysis.

Introduction

In the spring of 1971, an interdisciplinary team of marine researchers gathered at Eniwetok Atoll (now "Enewetak"), Marshall Islands to conduct the most comprehensive study of a coral reef undertaken until that time. This expedition resulted in significant advances in the understanding of coral reef metabolism and ecological function.

The name of the expedition, *Symbios*, was chosen as a metaphorical reference both to the symbiotic relationships that characterize coral reefs and to the symbiotic relationships that the late Dr. Robert E. Johannes, the Chief Scientist and driving force behind the expedition, thought should occur among scientists in ecological research. In retrospect, *Symbios* seems to be a clear demonstration of the importance of a well executed collaborative, interdisciplinary approach to undertaking scientific research. Our review shows that this expedition is now regarded as a significant contributor to our understanding of coral reef metabolism and ecological function.

The idea for the *Symbios* Expedition was developed jointly by Robert E. Johannes and Lawrence R. Pomeroy, who were colleagues of Dr. Eugene P. Odum in the University of Georgia's Institute of Ecology. Odum was a renowned pioneer in the field of ecology who, with his equally regarded brother, Howard T. Odum, conducted a remarkable study of coral reef metabolism at Enewetak in the Marshall Islands (Odum and Odum 1955; see also Barile 2004, who has provided a retrospective analysis of the Odums' study). The Odums' monumental monograph notwithstanding, relatively little was known in the 1960s about community metabolism of coral reefs, and Johannes and Pomeroy saw the value of building on the Odums' work. Their aim was to gather an interdisciplinary team of scientists to assess the community metabolism of an entire atoll. The initial objectives of *Symbios*, as presented in the original grant proposal to the U.S. National Science Foundation (NSF), are summarized in Table 1.

Table 1. Initial *Symbios* Proposal Objectives

1. Monitor changes in [chemical and biological] characteristics of seawater as it moves from the open ocean across the windward reef at site one and from the lagoon across the leeward reef at site two.
2. Conduct biological surveys across both reef transects to establish what species may exert quantitatively significant influences on nutrient and/or energy flux in these communities.
3. Determine the effects of the addition of nitrogen and phosphorus on reef community metabolism.
4. Measure changes in oxygen, nitrogen, and phosphorus levels in water flowing across the reef before and after the removal of the large reef herbivores (and coincidentally, the removal of large amounts of nitrogen and phosphorus).

In 1969, with the advice of Dr. W.J. Wiebe and others, Johannes and Pomeroy began the immense task of planning the expedition. According to the

original proposal, the expedition was to take place at Ant Atoll in the Caroline Islands because Enewetak was deemed too small and ill-equipped for such a large operation. As it turned out, it was logistical difficulties with Ant Atoll that led to the switch to Enewetak Atoll, in what was then the U.S. Trust Territory of the Pacific. Logistical support there was better, partially because of the Eniwetok Marine Biological Laboratory (EMBL), supported by the U.S. Atomic Energy Commission (AEC) and directed by Dr. Philip Helfrich.

The expedition was planned as a two-month-long deployment. The *R/V Alpha Helix* (Fig. 1), an NSF-supported research vessel operated by the Scripps Institute of Oceanography (SIO), would remain docked and be used as a floating. An additional group in a shore party would occupy facilities abandoned after the end of the nuclear weapons testing program a little more than a decade before.

Figure 1: The R/V Alpha Helix at Japtan Island pier, Enewetak Atoll. (Photo courtesy S.B. Betzer).

The arrangement worked very well. The ship served as sleeping and eating quarters for half of the scientific party. The ship's laboratories were modern and adequately equipped. Thanks to the creative expertise of the ship's chief electrician, Merle Post, a cable running from the ship provided power to shore buildings, which were used as additional laboratories, and eating and sleeping quarters for the shore party. Thus, the ship's scientific and logistical capabilities were strongly leveraged for a larger scientific party.

The complex logistics of the operation were supported either with direct funding or logistical support from the NSF, the AEC, the SIO, the Janss Foundation, and others. In interviews, *Symbios* participants point to the ingenuity and diligence of Helfrich, Johannes, Pomeroy, and the ship's crew for ensuring the success of the expedition despite the logistical obstacles presented by gathering a 23-person research team (Table 2) in a remote location to carry out such an enormous task.

[1]Deceased

This expedition has, until now, neither been documented for the historical record, nor has its impact on the field been evaluated through citation analysis, which involves the use of citation data for "the construction and application of a wide range of 'bibliometric' indicators of the 'impact,' 'influence' or 'quality' of scholarly work" (Moed 2005). This is not surprising, because scientists, whose primary interest is in the original research they conduct, rarely concern themselves with such things. Thus, we are typically left with only vague notions as to the scientific accomplishments of a given project and the factors that contributed.

The present project aims to paint a picture of the *Symbios Expedition* from its conception and execution through how its scientific results influence our present understanding of coral reefs. We show how its participants now perceive it and most importantly, how *Symbios* science has affected science in general in the last 35 years. As an exercise in the history of science, we hope this

project not only provides better documentation of the *Symbios Expedition*, its successes and the factors that enabled to them, but also leads to other similar studies for other research efforts.

While this project has scholarly aims, we hope that it may also come to the attention of the lay public and students interested in coral reef science.

Approach and Methods

This project had two components, the first being to provide historical documentation using traditional approaches, and the second being to conduct a citation analysis of *Symbios* publications and to assess their scientific impact. (Space limitations here will require us to report on these more fully elsewhere.)

We collected reference materials such as maps, ship logs, and research publications for historical documentation and to gain insight into the logistics of the expedition. Much of this was already in the SIO Library's Archives. The rest will be contributed to that collection. We also gathered from participants over 1600 photos taken during *Symbios* or related to *Symbios*. These provide insight into the living and working conditions of the expedition and help to demonstrate the social dimensions the participants experienced. Finally, we interviewed *Symbios* participants who added detail, perspective, and color to the historical record, and give insight to the reasons for the success of the expedition. Eleven interviews were conducted and transcribed. Participants were asked a series of similar questions but did not have them in advance, nor did they see the interviews conducted for the other participants. For example, we asked each individual what they thought the most significant scientific results of the expedition were, so that their answers could be compared to the results of the citation analysis. Transcripts were made of each interview.

We used citation data and network analysis tools to provide a quantitative understanding of the impact of the science of *Symbios* on scientific understanding. We first assembled a reference list of all papers we could identify that were uniquely or partly the result of research conducted by *Symbios* participants. Both peer-reviewed and non-peer-reviewed literature were included. Using the *ISI Web of Knowledge* (WOK*)*, we compiled citation counts for all peer-reviewed publications that were direct results of the expedition. Unfortunately, book chapters and other non-peer-reviewed publications are not as well covered by the WOK and were not included. The refereed *Symbios* publications were used for analysis of citation frequency and persistency, based on total citation counts and the years in which those citations occurred.

Citespace II, a network visualization tool developed by C. Chen at Drexler University, was used to create citation networks of *Symbios* publications and also to help determine if *Symbios* publications constituted pivotal points in coral reef literature. To create a network, we imported all the resulting publications of a general search into *Citespace II,* and allowed the program to determine which publications were turning points in the literature (pivotal points) based on when, where, how often, and by whom the publication was cited.

Results and Discussion

As was noted above, our approach to assessing the *Symbios Expedition* involved both the more qualitative approach of interviewing participants with the quantitative approach of doing the citation analysis. We felt that this would give us a way to gauge participants' impressions of the scientific accomplishments of the expedition with a wider measure of its impact on the scientific literature.

Oral Interviews. Interviewed participants were in consensus about several key facets of *Symbios*. First, all concluded that the expedition made major contributions to the understanding of the nitrogen cycle and metabolic function of coral reefs. This was verified by citation analysis (see below). Second, those interviewed felt strongly that the interdisciplinary, team approach to research embodied by *Symbios* was a critical characteristic that contributed greatly to Symbios' productivity. Third, the leadership of the late Dr. Robert E. Johannes was frequently cited as a major factor in fostering the scientific vision, cooperative spirit and interdisciplinary collaboration of Symbios. Moreover, interviewees noted that Johannes inspired younger scientists and graduate students, and made a concerted effort to involve women in a major marine science expedition, which was not characteristic at the time. (We believe that the two women who participated in the expedition were likely to have been the only women to have lived on the atoll in the 25-year interval since the Marshallese were expatriated in 1946.) Finally, participants also noted that Pomeroy and Helfrich played essential leadership roles as well.

Although Johannes had died before this retrospective project began, we were fortunate in obtaining an oral interview with him conducted by Dr. Jan Saap. While Johannes did not reflect on the administrative and leadership issues he encountered at all phases of the expedition, it is readily apparent how his enthusiasm for the *Symbios* science was "infectious."

Most interviewees felt that while the scientific objectives of *Symbios* were clearly defined and adhered to throughout the course of the expedition, good communication among participants allowed for "mid-course changes" to improve sampling protocols or take advantage of serendipitous discoveries. The two-month duration of the expedition allowed researchers to modify and repeat field experiments - another major reason cited for the expedition's success. Regular team meetings were held to assess progress and make necessary adjustments. Thus, when flux studies showed reef nitrogen export rates consistent with unexpectedly high rates of nitrogen fixation, it was decided to obtain by rush order the necessary supplies to measure nitrogenase using the acetylene reduction method. Given the logistical support offered by the AEC such as biweekly flights to Enewetak, it was feasible to obtain such critical supplies quickly and for individuals who were not part of the scientific party to join the expedition for a short interval. Thus several scientists from the University of Hawaii also came to conduct shorter complementary studies.

The excellent logistical support provided by SIO, NSF and AEC were mentioned by most interviewed as essential features that enabled *Symbios*' overall productivity. Because Helfrich also directed the AEC's EMBL, he had excellent relationships with key AEC managers in Washington and was able to facilitate logistics.

The other most significant reason for success, according to *Symbios* members, was the fact that the expedition was organized as a team effort, with individuals from widely varying academic backgrounds. At that time, team-oriented ecological studies were uncommon. Pilson said this of the team approach to *Symbios*, "Having a common objective where everybody was there to achieve a goal [was important] and people bring there own interests, their own perspectives to that. But they all wanted to see the enterprise succeed. So there's a certain natural dynamic when people are all keen on making it work." Helfrich said that it was crucial "being able to bring together a lot of scientists, each of whom had a little bit different perspectives and angles on a study like this, and seeing the dynamics of those scientists in the field together." Meyer said the following about of the need for working as an interdisciplinary team in ecological research, "It seems to me that if we are to understand the complexity of the world around us we need to have that diversity of approaches and understanding of the systems. They're complex systems and it's really hubris to think that only one person can truly understand them."

One of the remarkable features of *Symbios* was that it gave younger scientists, including the senior author of this paper, an incredible opportunity to work in a stimulating research environment with top-notch mentors. Meyer, for example, went on to a very distinguished career in stream ecology at the University of Georgia. In her interview, she cited *Symbios* as an important experience in her scientific development and networking that gave her confidence later on. Dr. Susan B. Betzer, on the other hand, said that she learned from *Symbios* that a research career in the ocean sciences was not for her. While she later finished her Ph.D. at the University of Rhode Island (and did include *Symbios*-based research in her thesis), she ultimately obtained an M.D. degree from the University of Miami and still is a practicing physician.

Citation analysis. As we noted above, the participants had their impressions of what the highest impact research conducted was. Citation analysis gave us an opportunity not only to reconcile their impressions with an objective metric, but also allowed us to gain a broader profile of the impact of *Symbios* research.

Symbios participants published nine peer-reviewed papers that related not only to the expedition's major goals but also other topics (Table 3). Many more non-peer-reviewed papers were also published, but they do not lend themselves to citation analysis because they are not well represented in ISI WOK databases.

Table 3. Publications or theses using data from *Symbios* (full citations appear in References).

Betzer (1972)	Pilson and Betzer (1973)

Helfrich and Allen (1975)	Wiebe et al. (1975)
Knutson et al. (1972)	

Fig. 2 is a *Citespace II* network created using topic search terms *coral** and *nitrogen*. All publications and corresponding citation data resulting from a Web of Knowledge search using those terms were imported into *Citespace II*, and then analyzed to produce the citation network shown. Nodes represent publications and links represent citations. Rings within nodes represent citations received within time intervals; the larger the node, the more citations it has received from other publications in the network. Pivotal points that are *Symbios* publications or authored by *Symbios* members are noted, with *Symbios* publications noted in bold text. Citation counts

showed high citation rates for all publications, including 738 total citations for these refereed publications.

We do not have sufficient space to report on this topic fully here, but many of the *Symbios* papers are still cited over three decades after publication. Our analysis also showed high persistence for *Symbios'* refereed publications with a mean of 16 citations per publication since the year 2000.

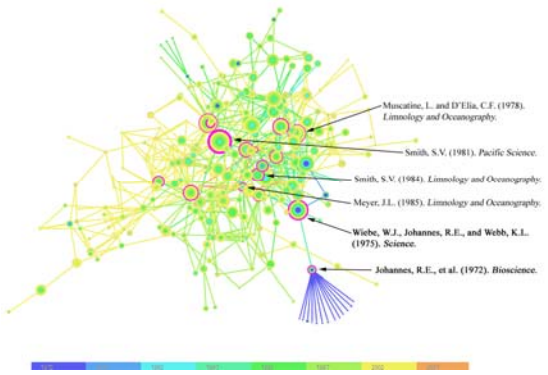

Figure 2. Citespace II network created using topic search terms coral* and nitrogen. (From Harris 2007).

The significant role of serendipity in scientific discovery is also apparent. One unexpected finding was that "Coral Chronometers…," Knutson, Buddemeier, and Smith's 1972 paper on growth bands in corals was the most highly cited publication, largely because of present interests in climate change that were unanticipated in 1971. Smith was only one of two *Symbios* members interviewed that mentioned that paper as a significant result. The research on which it was based was not a core activity of the expedition and was rather done "on the side," as were several other notable *Symbios* publications.

We believe that formal retrospective assessments of research productivity ought to be done more often. Most importantly, such studies provide useful documentation of the value of publicly funded research and the importance that serendipitous discoveries play in basic science. We also encourage more formal study into how large research projects are conducted and managed. Clearly, the team-oriented research of *Symbios* benefited from excellent conceptual and ongoing leadership, good administrative and logistical services, flexible adaptation to changing needs and opportunities, and a remarkably cooperative and team-oriented scientific party. We believe that the *Symbios Expedition* serves as a useful positive example for others to emulate in the future.

Acknowledgments

We thank SIO Archivist Deborah Day, Jan Saap and *Symbios* participants who helped. R.E. Turner and W.J. Wiebe made comments on the manuscript. C. Chen of Drexler University helped with us use the *CiteSpace II* program. Michael Reeve of the NSF's Division of Ocean Sciences provided a modest but critical amount of funding (NSF OCE 0500134) for this project.

Holocene reef accretion along the north side of Bahia Enriquillo (western Dominican Republic): unique insights into patterns of reef development in response to sea-level rise

Abstract. Well-exposed reef outcrops along the northern side of the Enriquillo Valley record continuous reef accretion between ca. 9,000 and 5,000 CalBP, when the bay was closed off from the open Caribbean. All the zones of present-day Caribbean reefs are well represented, and facies geometry provides valuable information about both paleo-environmental conditions and changing sea level. Suppressed coral-growth rates, coral distribution/shape, and patterns of bioerosion all point to elevated sedimentation and nutrient influx. Radiocarbon dates, combined with careful stratigraphic analysis, tell a story of early transgression under a regime of rapidly rising sea level followed by regression as sea level slowed and the shallow reef built out over deeper mixed- and massive-coral zones.

Key words: Holocene; fossil reef; reef accretion; sea level, bioerosion

Introduction

The Enriquillo Valley sits on the south-central coast of Hispaniola near the border between the Dominican Republic and Haiti (Fig. 1). During the early Holocene (ca. 9,000 CalBP), the embayment was open to the Caribbean, and coral reefs flourished in a low-energy setting that was exposed to at least periodic intervals of high sedimentation from the steep mountains flanking the bay. By 5,000-4,000 years ago, the bay had closed off due to sedimentation from the Rio Yaque del Sur and possible landslide activity (Mann et al. 1984; Greer and Swart, 2006). Evaporation lowered lake level to its present –42m, exposing the reefs. Arroyos have exposed continuous outcrops that span the entire zonation scheme from shallow, branching corals to deeper-water platy species. This paper describes the general character of the reefs, using a 450-m long exposure at Cañada Honda as the primary example. It then considers the possible environment of deposition based on both reef-community structure and characteristics of individual corals. Finally, it uses the three-dimensional facies pattern, along with radiocarbon ages from the outcrop to address the response of the Enriquillo reefs to rising sea level.

Methods

The outcrop was surveyed using a LaserTech Impulse200 instrument that determined vertical and horizontal intervals to within 1-3 cm. The survey was referenced to permanent markers located by differential GPS (Delorme Earthmate receiver and PostPro softwatre). Reef facies (Fig. 2) were initially defined based on visual estimation of species and point counting of corals at 20-cm vertical intervals along six transects. More detailed measurements were made in 53 meter-square quadrats (4870 data points) along 16 vertical transects. Coral statistics were analyzed within facies to verify or adjust the original boundaries.

Massive corals were divided into three primary shapes: hemispherical (the most common shape on modern reefs), conical and columnar. The shape of the colonies encountered in the quadrats were recorded and used to tie shape preference by species and overall within particular outcrops. A well-defined storm layer within the outcrop (Fig. 3) provides a time line that was used to characterize the morphology of the reef. It also provided an instantaneous surface below which we examined coral taphonomy and bioerosion by coral species and shape. Radiocarbon dates from corals just beneath the storm layer across the outcrop confirm the synchronicity of the event and date it at 9,500-9,000 CalBP.

Results

A total of 27 coral species (plus two *Millepora* species) were identified in the Enriquillo Valley reefs. The relative abundance of the most important species

* includes a variant with smaller polyps: aka Mini-*Montastraea*

is summarized in Table 1. The facies exposed in the outcrop represent all the major coral zones found on modern Caribbean reefs (Fig. 2). Within the branching coral zone, *Acropora palmata* is replaced by *A. cervicornis*, probably because of the low wave

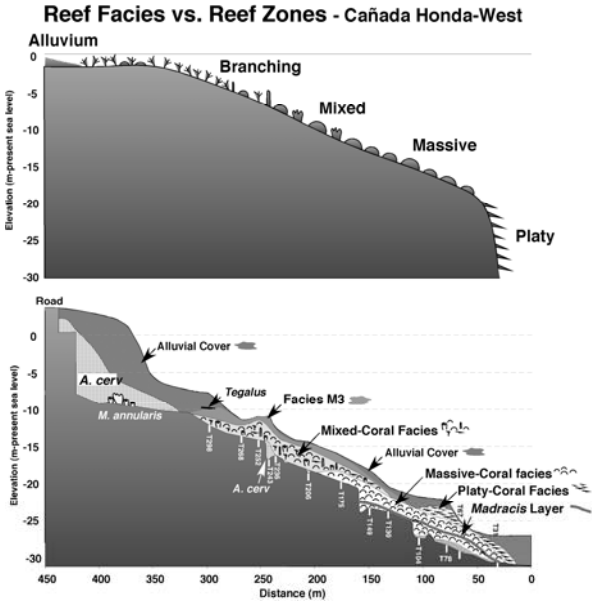

Figure 2: Cross-sections of a modern Caribbean reef (upper) and facies within the outcrop at Cañada Honda (lower)

Figure 3. Photograph of a storm layer dominated by *Madracis* spp. Note how many of the corals lean toward the right (i.e., downslope), reflecting disruption as the detrital layer was put in place.

energy in the protected embayment. Most of the coral appears to be either in place or simply compressed by collapse and burial. The oldest *A. cervicornis* colonies are found midway along the outcrop and the species extends to the uppermost part of the exposure, reflecting gradual transgression as sea level rose. Coral diversity was greatest in the mixed-coral zone, which was dominated by *Siderastrea siderea* and lesser amounts of *Colpophyllia natans* and *Montastraea* spp. (Table 1; Fig. 4). Corals in the deeper massive-coral zone were more evenly split between *Montastraea* spp. and *Siderastrea* spp. In the platy coral zone, the dominant species are *S. siderea* and *M. franksii*. Sediment made up 32-66% of the reef interior.

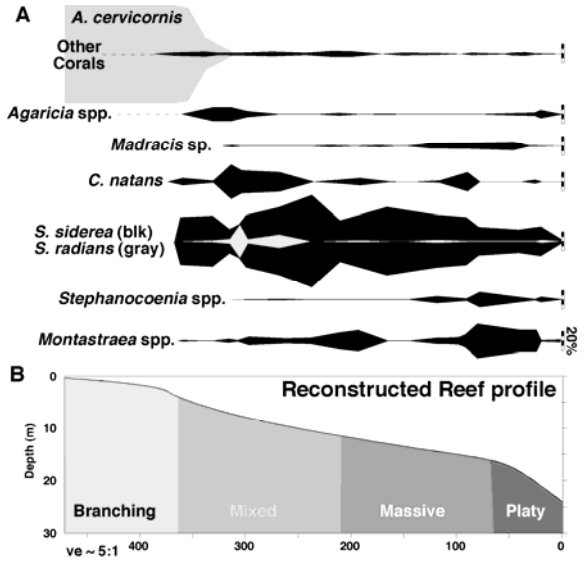

Figure 4: Reconstructed reef profile for the reef exposed in Cañada Honda (below). The coral abundance within facies and in the corresponding environments on open Caribbean reefs is shown by the Mae West diagrams at the top.

The massive-coral zone is interrupted by a layer of *Madracis* sp. (Fig. 3) that was initially deposited during a storm event 9,400-9,000 years ago. While there is evidence of recolonization and possibly additional debris emplacement later on, the base of the layer undoubtedly reflects a short-lived interval that represents a time line through the reef. This layer allows us to reconstruct the morphology and paleo-depths along the reef at that time. It also provides an opportunity to assess the relative importance of live versus dead coral along the reef at any one time. Preliminary studies based on the taphonomic condition of the buried corals (pristine or near-pristine corals are assumed to have been alive at the time of burial; those with significantly altered or encrusted surfaces were scored as "dead") infer that approximately half of the coral community was alive before the storm event that buried the entire forereef profile. We can use this value to "adjust" the quadrat data shown in Table 1 to approximate live-coral cover on an equivalent modern reef. Based on these numbers, live coral cover probably ranged from nearly 50% in the branching-coral zone to between 16 and 33% along the rest of the reef. Whether we use the raw quadrat data or the numbers adjusted by the taphonomic estimates, the percent cover along the Enriquillo Valley reefs approaches what is seen on modern Caribbean reefs, despite the protected nature of the embayment and the high likelihood of elevated sedimentation and nutrient loading.

Higher sedimentation is supported by three lines of evidence. First, the growth rates of *Siderastrea* spp. and *Montastraea* spp. are generally depressed

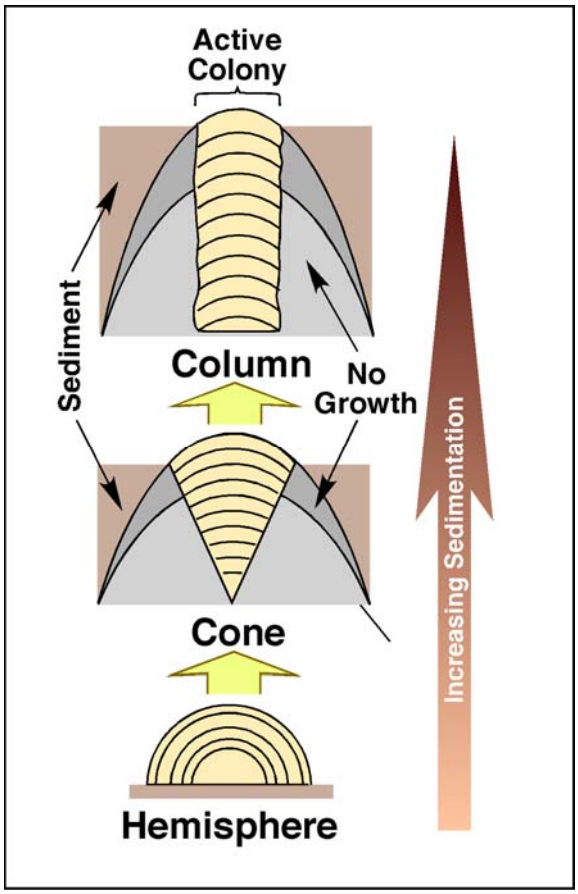

Figure 5. Effects of increasing sedimentation on coral shape in Bahia Enriquillo. On normal, oligotrophic reefs exposed to less sediment, hemispheres dominate. As the rate of sedimentation increases, polyps near the base of the colony will increasingly be overcome and lateral colony extension will be reduced. As a result, coral shape will gradually shift toward conical and columnar forms until a point at which sedimentation becomes so severe that the colony ceases to be viable and is totally overwhelmed.

(1-3 mm/yr) compared to the published rates for the same species at similar depths in the open Caribbean (5-10 mm/yr). Second, coral shapes are rarely hemispherical in outcrop. Conical and columnar growth forms are much more common. It is presumed that as sedimentation increases, lateral colony extension will be more difficult (Fig. 5). As a result, coral shape will shift from hemispherical to conical to columnar as coral bases are increasingly buried by sediment. In Cañada Honda, *Montastraea* spp. tends to be columnar, compared to a more conical growth form for the more sediment-tolerant *Siderastrea* spp. (Fig. 6). In an outcrop near Las Clavellinas (LC in Fig. 1), sedimentation rates are higher. In response, *Siderastrea* spp. shifts to a columnar form and *Montastraea* spp. is virtually absent, following the expected relationship between form and sedimentation. Finally, bioerosion in the Cañada Honda corals is higher and involves different

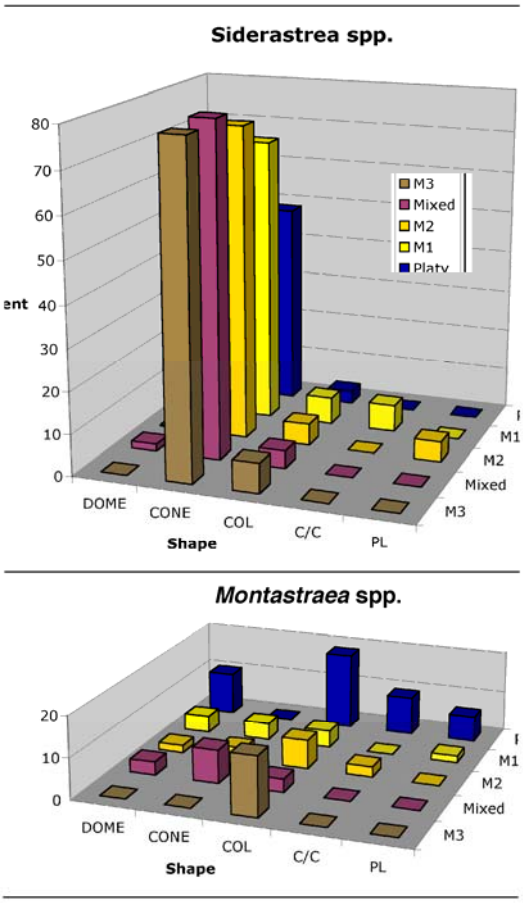

Figure 6. Graphs of coral shapes associated with the two dominant genera in the reef. The more sediment-tolerant species of *Siderastrea* tend to be conical, reflecting some difficulty with sedimentation. *Montastraea* spp. are even less tolerant and show a greater tendency toward columnar forms.

organisms than are typical of open-Caribbean settings. Bioerosion showed a general decrease with paleo-depth, similar to what has been found on open-Caribbean reefs. However, on a more general level, the difference between the borer communities at the two sites were statistically different at a value of $\alpha<.001$. The dominant borers in the Bahia Enriquillo corals were lithophagid molluscs. This contrasts dramatically with the greater importance of sponges in corals sampled from the US Virgin Islands (Fig. 7). This is consistent with past studies that have tied boring bivalves to well-documented high-nutrient environments (Highsmith 1980; Sammarco and Risk 1990; Perry and Hepburn 2007). Another indication of both high and episodic sediment stress is the abundance of colonies the reflect periods of burial separated by intervals in which the coral could build laterally over the remaining surface (Fig. 8).

On a larger scale, the overall facies geometry that is preserved in the outcrop (Fig. 2) reveals a change in accretionary style over time. Along the lower and

Figure 7. Photographs of coral slabs from Cañada Honda (left) and Cane Bay (St. Croix, USVI – right). In the more protected and higher-sediment/nutrient environment of Bahia Enriquillo, lithophagid molluscs dominated, compared to a borer community dominated by sponges in the open Caribbean.

central portions of the outcrop, coral date between 9,000 and 7,000 CalBP, a time when sea level was rising very rapidly (Fig. 9). Facies generally deepen upward (from massive to platy). This pattern is repeated in the central part of the outcrop, where facies change upward from massive to mixed corals– see Fig. 9 lower right photo). Later on, as sea level slowed, a gradual shift toward a regressive pattern emerges.

Discussion

The spectacularly exposed reefs in the Enriquillo Valley provide a unique opportunity to examine the internal structure of Holocene reefs at a level of detail impossible in cores. The species diversity within these reefs was surprisingly high, given the low energy and high sedimentation they experienced. This presumption is supported by the shift from *A. palmata* (which has no biological mechanism for sediment removal and relies on wave energy) to *A. cervicornis*, as well as retarded growth rates (1-3 mm vs 5-10 mm), the general lack of hemispherical colonies (except in *Colpophyllia natans*), and the dominance of lithophagid molluscs that require high nutrient levels to support their metabolic needs.

This high diversity flies in the face of modern paradigms that stress low coral abundance and diversity on reefs exposed to high sedimentation. The "pancake" morphology (Fig. 8) that is common

Figure 8. Photograph of "pancake" coral morphology. Each interruption in upward extension is interpreted as partial burial by sediment during storms that either delivered more sediment from land or, less likely, shifted it in from adjacent environments.

in all outcrops reflects high but periodic sedimentation. The present climate is very dry, but is seasonally interrupted by intense, flashy rains typical of a desert region. If this climate prevailed in earlier Holocene times, the high coral diversity may reflect clearer water in the intervals between rains. Greer and Swart (2006) have proposed variable rainfall on a decadal scale. If this extends to shorter periods of time, then the higher-than-expected diversity and abundance numbers may reflect "longer intervals of boredom separated by brief episodes of terror". Superimposed on this were the much larger events reflected in the storm-debris layer that is dominated by *Madracis* sp. (Fig. 3). Alternately, we may have to re-examine our existing ideas about sedimentation and coral diversity. Perhaps reefs that developed in a regime of long-term sediment stress were able to adapt, in contrast to the situation on modern reefs exposed to anthropogenically induced conditions.

Whatever the answer to this dilemma, the exposures at Cañada Honda allow us to address these and similar questions at a level of detail that was previously impossible. On a larger scale, the pattern of early transgression followed by a shift to regression as the rate of sea-level slowed provides strong support for the new and simplified Holocene reef model proposed by Hubbard (this volume).

Acknowledgement

This study was supported with funds from the Petroleum Research Find of the American Chemical Society, the Keck Geology Consortium and Oberlin College. Much of the work described above comes from careful work done by Oberlin undergraduates, in particular, Allicia Davis, Greg Lawson, Ali Stein, Josh Brewer, Jonathan Meed, and Jesse Oram. Karla Parsons-Hubbard helped with the taphonomic analyses, which have subsequently been improved by Hal Lesinsky

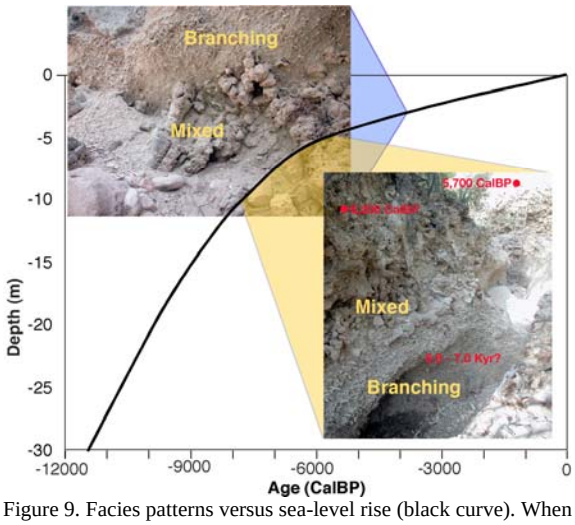

Figure 9. Facies patterns versus sea-level rise (black curve). When sea level was rising more rapidly, paleo-environments deepened upward (lower right photograph). As sea-level rise slowed, the shallow branching facies migrated seaward over the deeper mixed-coral facies. This demonstrates a pattern of transgression before 6-7,000 years ago, gradually shifting to regression.

Abstract. Shallow seismic profiling survey, bathymetric mapping, and ROV (remotely operated vehicle) observations were carried out to the east of northern Amami-o-shima Island (28˚24'N, 129˚38'E). The survey area is located in a northern part of the Ryukyu Island Arc and close to the present-day northern limit of coral reef formation in the northwestern Pacific. Irregularly-shaped mounds occur in the northeastern part of the survey area. These mounds appear to be composed internally of postglacial reef deposits which are covered with modern coral assemblages. Seismic profiles show that channels several hundred meters long are developed on the western margin of the mounds. The channels may correspond to eroded valleys formed during the last glacial period and are overlain by stratified sediments. This indicates that coarse siliciclastic sediments derived from Amami-o-shima Island were trapped in the channels and that limited sediments were transported into the eastern part, which may have allowed coral reef formation in that part during the last deglaciation.

Key words: Seismic profiling survey, Ryukyu Island arc, Postglacial, Fore-reef, Northwestern Pacific.

Introduction

The Ryukyu Island Arc extends from Kyushu to Taiwan, a distance of 1200 km, along the Ryukyu Trench where the Philippine Sea Plate is subducting beneath the Eurasian Plate (Fig. 1). The Okinawa Trough, a back arc basin (Shinjo et al. 1999), formed behind the Ryukyu Island Arc in the late Pliocene to early Pleistocene (Sibuet et al. 1998 and Park et al, 1998). The formation of the Okinawa Trough is one of the most important factors for initiation and development of coral reefs in Ryukyus because it has trapped siliciclastic sediments from the Eurasian Continent, which changed paleoceanographic conditions in this area from the 'mud sea' to the 'coral sea'. The warm Kuroshio Current enters the Okinawa Trough and flows northeastwards along the Ryukyu Islands. The current brings larvae and planula of hermatypic corals as well as heat. This enables coral reef formation throughout the Ryukyus, although the islands lie at relatively high latitudes compared with other reef sites (Iryu et al. 2006).

In this study, we present high-resolution seismic profiles of modern fore-reef on the shelf of the Ryukyu Island Arc. The survey area was located in a northern part of the Ryukyu Island Arc, northeast of Amami-o-shima Island. The survey area lies close to the present-day northern limit of coral reef formation in the northwestern Pacific which is situated at Tane-ga-shima Island (Iryu et al. 2006). This survey aims to delineate the lateral extent and depth distribution of coral reefs formed during the last glacial and postglacial periods at a marginal region of the reef province in the northwestern Pacific and to unravel the factors controlling initiation of coral reefs during the last deglaciation.

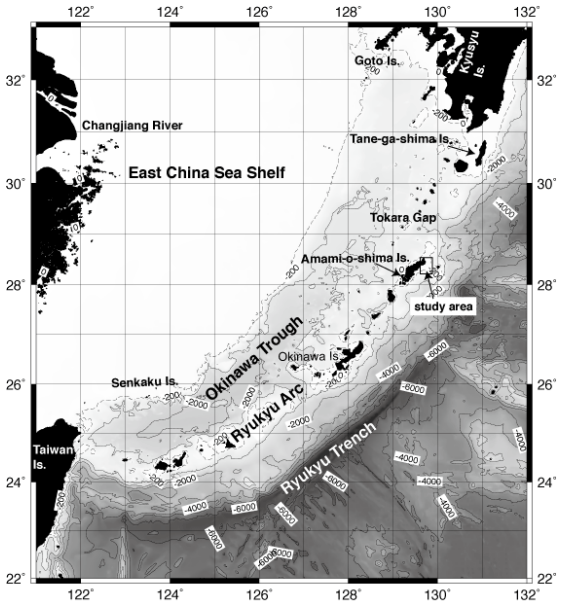

Figure 1: Bathymetric map of the Ryukyu Island Arc. Note the study area off Amami-o-shima Island which is close the present-day coral reef formation located at Tane-ga-shima Island.

Methods

The survey cruise was carried out by Dai-hachi Shofuku-maru (fisherman's boat with gross tonnage of 6.54). Seismic profiles were acquired by AA300 Boomer Plate system with 8 channels digital streamer cable. Data were collected using a 2-second-firing rate. Data were logged to SEG-D format using a CNT-2 digital acquisition system. The survey lines in a WNW-ESE direction ranged in length from 2 to 2.5 km, where water depth varied between 10 and 60 m (Fig. 2). The interval of the lines was about 100 m. The data were stacked before interpretation at onshore survey.

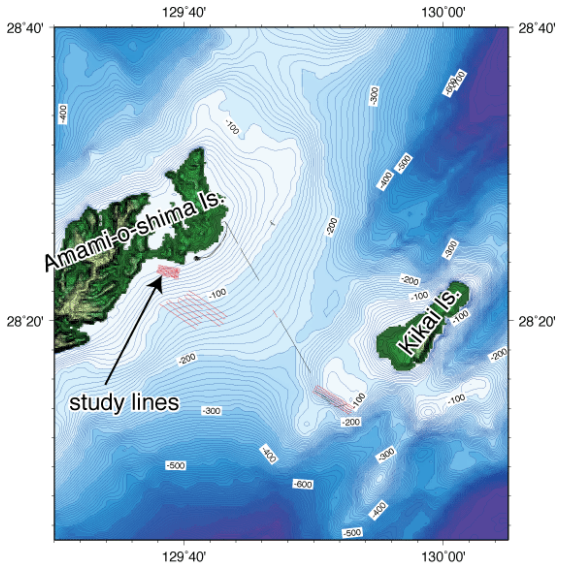

Figure 2: Seismic and bathymetric survey lines in the study area. The data of this study were obtained from shallow areas ranging in water depth from 10 to 60 m, to the east of Amami-o-shima Island.

Bathymetric surveys were conducted using a SeaBat 8101 multibeam echosounder along the seismic survey lines. After the seismic and bathymetric surveys, we obtained the video images using remotely operated vehicle (ROV) LBV150 SE (Nippon Kaiyo Co., Ltd). The ROV was deployed in the several areas on and around postglacial to modern fore-reef, where water depths ranged from 7 to 45 m and provided high-quality visual images of the reef deposits.

Results

The ROV video images and bathymetric maps indicate that the northeastern part of the survey area is characterized by presence of irregularly-shaped mounds (Fig. 3A). These mounds appear to be composed internally postglacial reef deposits which are covered with modern coral assemblages. In contrast, a flat seafloor extends in the western and southern deeper areas, consisting mainly of coarse sediments (Fig. 3B).

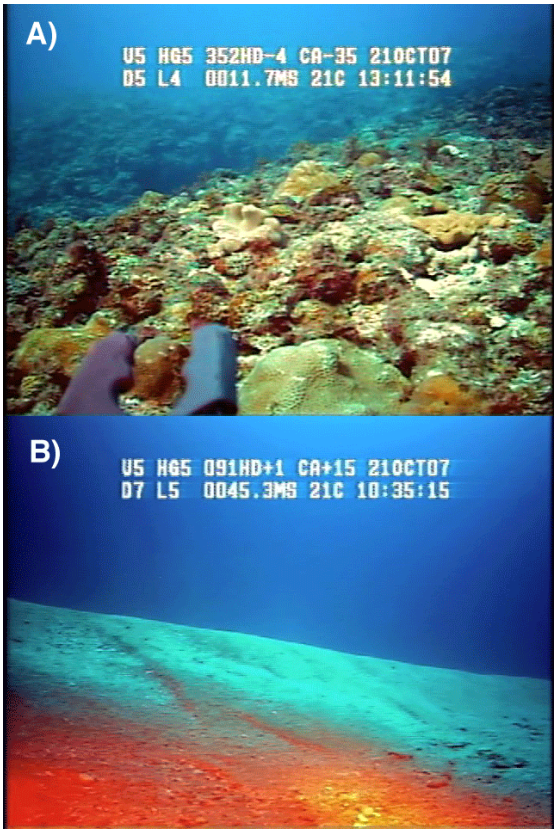

Figure 3: ROV video images. A) Modern coral reef at a water depth of 11.7 m in the eastern part of survey area. B) Flat sea floor composed chiefly of coarse sediments at a water depth of 45 m.

The reefs in Fig. 4 extend along the coastal line with a total span of > 1.5 km in the northeastern part of survey area. Spurs and grooves are arranged perpendicularly to the seaward margin of the reefs (Fig. 4) and extend for 1 km off the margin. The

grooves are several tens meter width and several meter deep. The base of the spurs and grooves are < 50 m water depth. We found similar irregularly-shaped mounds covered with modern corals in southern part of study area, where water depth is < 30 m. The mounds rimmed by spurs and grooves are < 150 m in a total span.

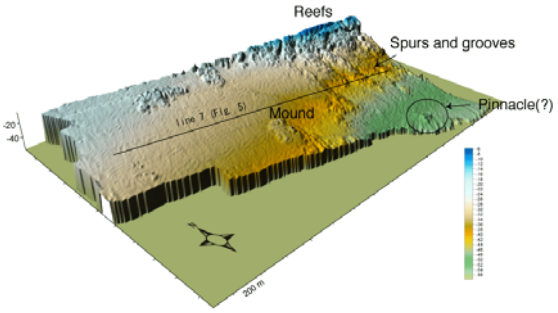

Figure 4: Oblique view of survey area. Irregularly-shaped mounds occur in northeastern area. The spur and groove structures with a N-S direction were observed. Note the locations of seismic profile in Fig. 5.

High-resolution seismic profiles show a distinct, irregularly-undulated reflector which can be traced throughout the survey area (Fig. 5). The reflector, beneath which the profiles are not clear, is overlain by the stratified sediments. The maximum thickness of the stratified sediments is 60 ms in two way travel time. The sediments showing continuous parallel reflections unconformably onlaps the irregularly-undulated reflector.

Channels are found on the western margin of the eastern part of the survey area where the irregularly-shaped mounds occur. The channel shown in Fig. 5 is 100-200 m in wide and can be as deep as 45 m if we assume that constant velocity of sediments is 1500 m/s. The channels have a north-south direction extending over several hundred meters. Channels of a similar size to this are found on other lines in the survey area (Fig. 6).

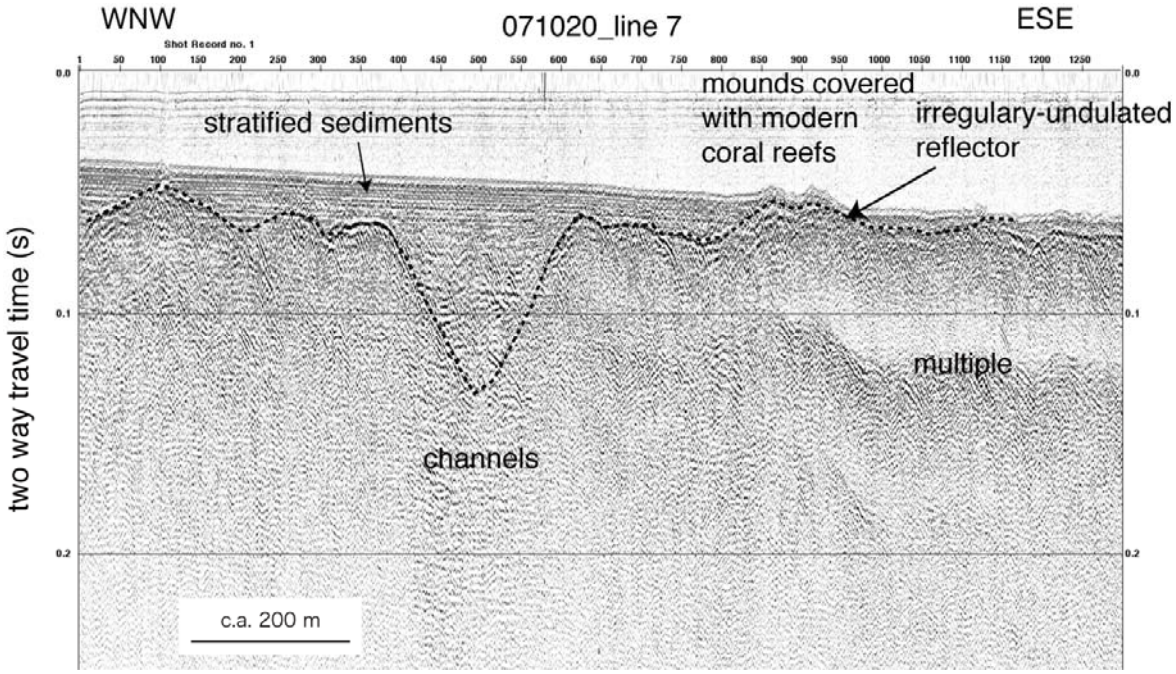

Figure 5: Stacked profile of 8ch MCS off eastern Amami-o-shima Island (Figs. 2 and 4). A distinct, irregularly-undulated reflector is recognized throughout the survey area.

Discussion

Unclear internal structures below the distinct, irregularly-undulated reflector contrast well with the overlying parallel continuous reflections. This indicates that the stratified sediments lie unconformably on the erosional unconformity surface (represented by the irregularly-undulated reflector) formed by subaerial exposure during the last glacial period. The ~45 m deep channels are likely to correspond to eroded valleys formed during this period, as well. The base of the stratified sediments is characterized by an onlap configuration, which suggests that the sediments with parallel stratification accumulated on the last glacial erosional surface during the postglacial sea-level rise. The thickness of the stratified sediments decreases eastward (Fig. 5); this indicates the sediment supply to the survey area came from the west (Amami-o-shima Island) during the postglacial period. Several channels are found on the western margin of the eastern part of the study area in which irregularly-shaped mounds composed of postglacial reefs covered with modern coral communities occur (Fig. 6).

Our data suggests that the coarse silisclastic

sediments derived from Amami-o-shima Island were trapped in the channels and this limited the transportation of sediments into the eastern part. This may have allowed coral reef formation in the eastern study area during the last deglaciation.

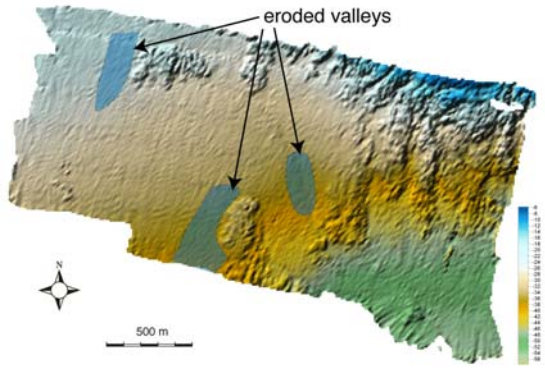

Figure 6: Bathymetric map showing the distribution of eroded valleys (blue area).

Conclusions

1. Internal structures of the modern fore-reef were revealed using a multi channel high-resolution seismic survey.
2. The ROV video images and bathymetric maps clearly indicate that the northeastern part of the survey area is characterized by presence of irregularly-shaped mounds of modern coral reefs and that the flat seafloor, consisting mainly of coarse sediments, extends in the southern and western area.
3. A distinct, irregularly-undulated reflector which may represent erosional surface formed in the last glacial period is recognized throughout the survey area.
4. The channels which may correspond to eroded valleys formed during the last glacial period are developed on the western margin of the eastern part of the survey area where the irregularly-shaped mounds occur.
5. The coarse sediments derived from Amami-o-shima Island were trapped in the channels, which limited sediment transportation into the eastern part of the study area. This may have allowed coral reef formation in this area during the last deglaciation.

The Darwin Point: a conceptual and historical review

Richard W. Grigg

University of Hawaii, Dept. of Oceanography, 1000 Pope Road, Honolulu, Hawaii USA

Abstract. The term "Darwin Point" is defined as the geographic or depth limit (threshold) beyond or below which coral reefs drown. Reef drowning occurs when net production of $CaCO_3$ or vertical accretion of the reef no longer keeps up with relative sea level. If sea level is rising very fast, then reef drowning can occur even if there is very low vertical accretion. If present ecological conditions were to change, due to a rise or fall in sea-level, geophysical uplift or subsidence, or Global Climate Change, the geographic location or depth limit of a Darwin Point would also change. In this paper, the history of the Darwin Point concept is reviewed and several examples are given of reefs and atolls that have drowned having exceeded a Darwin Point threshold. Such appears to be the case for: 1) guyots beyond the northwestern end of the Hawaiian Archipelago, 2) atolls that crossed equatorial latitudes due to plate movement in the Pacific during Cretaceous Time, and 3) many drowned reefs extant at the present time; a result of sea-level rise since the last Glacial Maximum 21,000 years ago.

Key words: Darwin Point, coral reef drowning, coral growth, bio-erosion

Introduction

Darwin Points define thresholds of reef drowning. A Darwin Point is reached when the net production or the accretion rate of $CaCO_3$ by reef building corals no longer keeps pace with relative sea level. In 1972, K. Chave (Chave et al. 1972) described net production of $CaCO_3$ as the $CaCO_3$ permanently retained by the reef. Reef drowning occurs when production rates due to coral growth are exceeded by rates of bio-erosion and physical induced loss, and/or rates of subsidence or sea level rise.

Application to the Hawaiian Archipelago

The Hawaiian Islands consist of a long and linear chain of volcanic islands, coral islands and atolls, which are slowly subsiding and gradually drifting (by tectonic displacement) to the northwest from tropical into subtropical latitudes and cooler water. The growth rate of reef building corals surrounding the islands should therefore decrease with increasing latitude within the island chain. At one point the growth of corals should no longer support and sustain atolls at sea-level. This point defines a threshold for atoll development. The research needed to test this hypothesis was conducted between 1978-1981 (Grigg 1982). Rates of gross production of $CaCO_3$ per unit area were measured from the first island of Hawaii to the last island in the Hawaiian Archipelago, Kure Atoll, a range of latitude of about 10 degrees (~19.5–29.5 N. Latitude). The data were collected at comparable stations and depths. All stations were located off southwest exposures off the islands or banks at depths of 10 m in areas of maximum reef development.

At each station, coral growth was measured by averaging the width of at least ten annual growth bands (Knutson et al. 1972) in skeletal cross sections of ten colonies of the most abundant species, *Porites lobata*. Colony mass accretion in kg $CaCO_3$ was calculated as the product of mean linear growth rate and mean colony density. Mean values of mass accretion for colonies of *P. lobata* were then computed for each island and multiplied by measures of mean coral cover for all species of coral, producing mean rates of accretion due to all corals in Kg $CaCO_3/m^2$/year (Fig. 1). *P. lobata* is considered representative of other Hawaiian coral because of its massive growth form, and because it is intermediate in growth rate (Buddemeier et al. 1974). It is also the dominant framework builder in the Hawaiian Archipelago (Grigg 1983).

All measures of growth were taken along axes of maximum growth in each colony. Estimates of coral bottom cover were taken from optimal areas, where rates of accretion were considered estimates of maximum gross production for corals. In optimal environments in Hawaii, rates of erosion and dissolution are small and gross production is a reasonable approximation of net production. In fact, estimates of calcification based on the method used here agree well with measures of net calcification based on alkalinity depression for comparable areas in Hawaii (Kinsey 1979).

The results of the study showed that islands drown at a point very close to 29 degrees north latitude, although consideration of historical patterns of sea-level change or climatic change may have periodically shifted this threshold, dubbed the Darwin Point, northwest or southeast in response to changing sea level or thermal structure (Grigg 1997).

The data illustrates that coral reef accretion declines linearly as a function of latitude from Hawaii in the southeast to Kure Atoll in the northwest (Fig. 1). Mean accretion rates of the reefs due to coral growth alone at the southeast and northwest extremes of the Archipelago were 11 mm/yr (15 kg $CaCO_3/m^2/yr$) and 0.2 mm (0.3 kg $CaCO_3/m^2/yr$), respectively. The accretion rate at Kure Atoll of 0.2 mm/yr is very close to zero and taking into account biological and physical erosion, it is reasonable to conclude that it is virtually zero. On a longer time scale, Kure Atoll will likely undergo drowning and join 12 other drowned atolls (guyots) that exist in a linear sequence to the northwest. These drowned features are known as the Emperor Seamounts and all were once thriving atolls southeast of a Darwin Point latitude. They range in age between 30 and70 Ma. Their geomorphology and fossil summits strongly suggest they were all thriving atolls before drifting northwestward past a paleo-Darwin Point. The Darwin Point thus separates the Hawaiian Archipelago into two approximately equal halves; islands that are presently at or above sea-level and those that have drowned. All sub-aerial islands are southeast of the Darwin Point; all drowned guyots are northwest of the Darwin Point.

Application to atoll drowning near the equator during Cretaceous Time

In 1993, the Ocean Drilling Program (ODP), legs 143 and 144, recovered cores from seven guyots in the northwest Pacific Ocean. Analysis of the cores showed that these volcanic edifices underwent prolonged volcanism (128-84 Ma), followed by subsidence, accumulation of shallow-water coral reef carbonates, emersion due to a sea-level fall, and then continued subsidence, submergence and eventual drowning. According to Peter Flood (1999), five of the seven guyots drowned at latitudes within 8 degrees of the equator having been transported there by plate movement during the Mid-Cretaceous. Flood ascribed the drowning events to be the result of the atolls entering a crisis zone (Darwin Point) near the equator where upwelling produced nutrient rich waters that inhibited carbonate production (Figs. 2 and 3). Flood also suggested that sea-level rise could have been an additional factor causing the drowning of these atolls. In support of this hypothesis, Schlanger et al. (1981) concluded that wide-spread mid-plate volcanism between 100-70Ma caused thermally induced uplift of the Pacific and Farallon plates leading to global Cretaceous transgressions (Fig. 4). Thus a shifting Darwin Point near the equator in the Western Pacific Ocean could be the explanation for the drowning of these and other atolls that were transported through equatorial waters by plate motion during Mid-Cretaceous time.

Application to a depth limit for the accretion of coral reefs

It is well known that the critical depth for the formation and accretion of coral reefs in optimal environments is generally found at depths between 30-50 m (Grigg 2006, Grigg and Epp 1989, Hopley 1982, Darwin 1962 Reprinted). In environments less than optimal, critical depth would be expected to be shallower. Critical depth as described herein may conceptually be viewed synonymously with a Darwin Point in the third dimension, e.g., a vertical Darwin Point. While this synonymy is somewhat semantic, the factor or factors producing a Darwin Point are not.

Because calcification rates in hermatypic corals are significantly greater than species lacking zooxanthellae, light has long been considered the primary factor setting the lower depth limit for the reef building process (Barnes and Chalker 1990, Wells 1957). This is particularly true for gross production of $CaCO_3$ by reef building corals (Chave et al. 1972). However, if depth limitation depends on the net carbonate production retained by the reef, then many other intervening factors such as temperature, turbidity, bio-erosion and mechanical losses due to waves must be considered. In whatever case, when net production is zero (assuming constant sea-level change) the over-all reef is at a drowning threshold or vertical Darwin Point.

Recent measures of a vertical Darwin Point have been made off Lahaina, Maui in the Au'au Channel in the Southeast Hawaiian Islands (Grigg 2006). The threshold depth of reef drowning there was found to exist at 50 m (Fig. 5). Below 50 m, the rate of bio-erosion of the holdfasts of the major reef building species, *P. lobata*, exceeded the growth of basal attachments causing colonies to detach from the bottom. Continued bio-erosion further eroded colonies until they were dislodged by bottom currents leading to their breakdown and ultimate formation of carbonate rubble and sand. Coral colonies of species that grow deeper than 50 m in the Au'au Channel, (some down to 120 m [Kahng and Maragos 2007]), do not permanently attach and accrete. A Darwin Point is reached at 50 m in the Au'au Channel, off Maui, because gross carbonate production minus bio-erosion is zero (Fig. 5). In an analogous manner, biological and mechanical erosion at Kure Atoll in the NWHI reduces a positive net rate of $CaCO_3$ production there to zero, giving way to a zoogeographic Darwin Point near 29° North latitude. Similarly, Darwin Point thresholds were surpassed many times along the outer edge of the Great Barrier Reef during the last transgression (Hopley 2006).

In summary, Darwin Points are found at both latitudinal and depth limits where the net production of $CaCO_3$ retained by the reef is zero relative to sea level. The critical depth for the entire reef is a Darwin Point, but it may be deeper for individual corals. Historically,

Darwin Points have existed since the evolution of reef building corals at the beginning of the Mesozoic Era. They have set both the zoogeographic and depth boundaries for coral reefs for 240 Ma and continue to do so. Interestingly, in 1837, while viewing the island of Moorea from an elevation of about 300 m above Point Venus on the island of Tahiti, both limits were conceived conceptually by Charles Darwin himself (Darwin 1851).

Abstract
For tropical corals, the projected decreases in seawater pH due to increasing atmospheric pCO_2 are predicted to reduce calcification by 8% to 40%, but little is known of the interactions with other physical conditions, or the effects on other biological processes. This study tested for the interactive effects of pH and temperature on the photosynthesis and calcification of corals using experiments in which pH was reduced (7.8), simulating year 2100 pCO_2 levels, and was crossed with two temperatures (27 ºC and 29 ºC). In 14-day incubations with *Pocillopora meandrina* and *Porites rus*, calcification was depressed ≥ 50% at 27 ºC and 700 ppm CO_2, compared to 27 ºC and 395 ppm CO_2, but was not depressed by high pCO_2 at 29 ºC; dark-adapted maximum quantum yield of PSII (F_v/F_m) was unaffected by the same treatments of temperature and pCO_2. Thus, while F_v/F_m in *P. meandrina* and *P. rus* is resilient to slight increases in temperature and high pCO_2, calcification shows temperature-dependent sensitivity to high pCO_2, notably with high temperature apparently conferring resistance against the short-term effects of high pCO_2.

Key words: Scleractinia, Calcification, Climate change, Photosynthesis, Temperature,

Introduction

The foundations of tropical reefs rely on the prodigious capacity of symbiotic scleractinians to calcify and to fix large amounts of carbon (Hoegh-Guldberg 2005). Rapid calcification by corals plays a critical role in coral reef function, because it leads to the formation of a massive, wave resistant framework that provides habitat for many taxa (Idjadi and Edmunds 2006). Understanding the factors controlling coral calcification is critical to project coral community structure into the a future strongly impacted by global climate change (GCC), and to elucidate the implications of global climate change (GCC) for the taxa that rely on coral structure as habitat.

Already, many coral reefs are in a state of decline (Hoegh-Guldberg et al. 2007) due in large part to the effects of multiple anthropogenic disturbances acting locally (Jackson et al. 2001) as well as regionally (Hoegh-Guldberg et al. 2007). Predictions of the biotic effects of GCC have identified temperature and partial pressure of atmospheric CO_2 (pCO_2) as factors with serious implications for marine ecosystems, specifically through increasing acidity of seawater (i.e., ocean acidification, or OA), and rising ocean temperatures (IPCC 2007). Current pCO_2 levels of ≈350-380 ppm are predicted to exceed 700 ppm by the year 2100, if "business-as-usual" CO_2 emissions are maintained (IPCC 2007). Such a dramatic increase will cause substantial declines in the pH, aragonite saturation state (Ω_a), and carbonate (CO_3^{2-}) concentrations of seawater, which in turn, will depress coral calcification (Hoegh-Guldberg et al. 2007). Multiple studies have shown a strong and positive relationship between coral calcification and Ω_a (Langdon 2000), with declines in Ω_a depressing coral calcification by 20-40% for a doubling of pCO_2 from current levels (Hoegh-Guldberg 2005).

In addition to the interest in the consequences of OA for corals, the effects of rising temperature have also attracted attention, with the majority of this effort focusing on thermal bleaching (Brown 1997). Surprisingly however, few studies have simultaneously tested the effects of increases in temperature and declining pH (OA) on coral calcification, and in those studies that have, conflicting results have been obtained. For instance, one study found that high temperature and low pH acted in positive synergy to further depress coral calcification (Reynaud et al. 2003), while another reported that coral calcification under summer temperatures (27 ºC) was less affected by pH than under winter (23 ºC) temperatures (Langdon and Atkinson 2005). Potentially, some of the complexity

in the synergistic effects of temperature and OA on coral calcification is a result of the tight association between calcification and photosynthesis (McConnaughey and Whelan 1997), such that the effects of temperature and OA on calcification might not be independent of the effects on photosynthesis (Gattuso et al. 1999).

The objective of this study was to explore the interactive effects of high temperatures and high CO_2 on the calcification and photosynthesis of corals. We selected *Porites rus* and *Pocillopora meandrina* for this analysis because these species are common in the lagoon of Moorea, French Polynesia, where they form branching colonies that are tractable to manipulation. A microcosm system was used to expose the corals to either ≈27.3 ºC or ≈29.4 ºC at pH levels of 7.8 or 8.2, with the low temperature falling close to the ambient temperature (28.4 ºC) when the experiment was conducted (April 2007), and the high temperature being close to maximum temperature occurring in the lagoon (29.9 ºC); the two Ω_a levels represent present day conditions and those expected within ≈100 years (IPCC 2007).

Methods

Incubations were conducted for 2 weeks in April 2007 using a design in which corals were placed into one of four tanks (each 135 l) that created two crossed levels of temperature and Ω_a. The outcomes of the incubations were assessed through calcification and photosynthetic efficiency (maximum dark-adapted quantum yield, F_v/F_m), and were analyzed with a Model I, two way ANOVA. The statistical replicates were coral branches collected from *Porites rus* and *Pocillopora meandrina* growing at 1-2 m depth in the lagoon of Moorea. For each species, one branch (3.5–6 cm long) was collected from each of 44 colonies that were separated by 3-5 m to increase the likelihood that they were unique genotypes. Following collection, the fragments were transported to the lab and prepared as nubbins by attaching them to plastic bases with epoxy (Z-Spar A788). Nubbins were then placed in flowing seawater for 12 h and monitored visually for signs of damage. Healthy nubbins from each species were assigned randomly to one of the four incubation tanks, such that every tank contained equal numbers (n = 11) of *P. rus* and *P. meandrina*. Nubbins were acclimated to tank conditions for 24 h at a mean temperature of 28.4 ± 0.5 ºC (± SE, n = 54), a mean pH of 8.2 ± 0.1 (± SE, n = 76), and a constant mean light level of 480 ± 87 µmol photons m^{-2} s^{-1} (n = 12) provided with lamps (described below).

During treatments, nubbins were maintained in tanks located indoors, with each fitted with a chiller, heater, and pump that mixed and aerated the seawater. The seawater was replaced partially each day (20 % d^{-1}) with unfiltered seawater collected from the lagoon. Two 1000 W metal halide lamps (Sylvania BT37, Metalarc) were suspended 0.5 m above the tanks to provide light intensities of 797 ± 14 µmol photons m^{-2} s^{-1} (± SE, n = 148, measured with a Li-Cor LI 193SA) on a 12:12 light:dark cycle. The light intensity was selected to be less than the intensity at noon (1,720 ± 370 µmol photons m^{-2} s^{-1}, n = 17) at the collection depth when the experiment was conducted. Each tank was fitted with a microprocessor-controlled regulator (Neptune Systems) that operated the heaters, chillers, and pH regulation system to maintained temperatures with a resolution of ± 0.2 ºC, and pH with a resolution of ± 0.1 unit. Using this system, the two tanks at the control temperature were maintained at 27.2 ± 0.4 ºC and 27.5 ± 0.3 ºC (± SE, n = 236 and 246, respectively), and the two at the high temperature were maintained at 29.6 ± 0.2 ºC and 29.2 ± 0.4 ºC (mean ± SE, n = 290 and 249, respectively).

The pH of the tanks was controlled by adding dilute HCL or NaOH, using pumps operated by the regulators. The pH was logged using pH electrodes (Orion 9156 BN-WP, calibrated every 12 h using NBS buffers) attached to the regulators, and the output of the electrodes was used indirectly to operate the pumps adding acid or alkali. Using this system, the tanks at control pH were maintained at mean levels of 8.17 ± 0.01 (±SE, n > 278), and the treatment tanks were maintained at mean levels of 7.81 ± 0.05 (± SE, n = 587), and 7.82 ± 0.06 (± SE, n = 587). In addition to monitoring the pH, DIC parameters (Table 1) were assessed every 2-3 d by Gran titrations that were used to calculate total alkalinity (TA); TA and pH were used to calculate Ω_a using the CO2SYS program (Lewis and Wallis 1998) and the NBS buffer scale. The accuracy of the TA values was assessed using Certified Reference Materials (from Scripps Institute of Oceanography), which revealed downward discrepancies of 6% for TA and 11% for total DIC.

Calcification was assessed as the change in mass of the carbonate skeleton as determined by buoyant weighing, and was normalized to the coral area (µg mm^{-2} d^{-1}) determined by wax dipping (Stimson and Kinzie 1991). The maximum dark-adapted quantum yield of PSII (F_v/F_m) was measured before and after incubation for *Pocillopora meandrina* and *Porites rus* using a pulse-amplitude-modulation fluorometer (Diving PAM, Walz, GmbH) that was maintained at constant instrument settings for each species. Based on the results from previous studies, corals were dark adapted for ≥ 3 h prior to measuring F_v/F_m.

The results were analyzed using a two-way ANOVA, in which temperature and pH were fixed factors, and nubbins were statistical replicates. To

gain insight into the variation in calcification between each pH level within each temperature level (i.e., where a significant interaction was detected), a Student's t-test was subsequently applied, but as this represented an unplanned post hoc analysis, the results should be interpreted with caution. The statistical assumptions of normality and homoscedascity were tested through graphical analyses of the residuals, and all statistical tests were accomplished using JMP software (Version 7, SAS Institute Inc) running in a Windows environment.

Results

Of the 44 *Porites rus* nubbins used in the experiment, all appeared healthy throughout the incubations and, although slight paling did occur in all tanks, this was not associated with significant changes in F_v/F_m as compared to freshly collected corals ($p > 0.90$). *Pocillopora meandrina* appeared to be more sensitive to the incubation conditions, with some nubbins showed paling in the control and treatment for both pH and temperature conditions.

Calcification rates

For *Porites rus*, mass increased by 33 to 110 µg mm^{-2} over the 14 d incubation in all treatments (Fig. 1), and growth was affected significantly by a temperature x pH interaction ($F = 17.554$, df = 1,39, $p < 0.001$), as well as pH ($p < 0.001$), but not temperature ($p = 0.150$). At 27 °C, mean calcification rates were reduced 70% from 7.9 ± 0.8 µg mm^{-2} d^{-1} (± SE, n = 10) at pH 8.18, to 2.4 ± 0.7 µg mm^{-2} d^{-1} (± SE, n = 11) at pH 7.80, and this difference was significant ($t = 6.768$, df = 19, $p < 0.001$). At 29 °C, mean calcification rates were unaffected by pH ($t = -0.219$, df = 20, $p = 0.828$), and they changed only slightly from 6.0 ± 0.6 µg mm^{-2} d^{-1} (mean ± SE, n = 11) at pH 8.18, to 6.3 ± 0.9 µg mm^{-2} d^{-1} (mean ± SE, n = 11) at pH 7.80.

For *Pocillopora meandrina*, four nubbins (9% of the total) were removed from the analyses of calcification rate because they lost weight and displayed low values of F_v/F_m (< 0.500) that are indicative of poor health. Calcification rates for this species were also affected significantly by a temperature x pH interaction ($F = 4.819$, df = 1,36, $p = 0.034$), but neither of the main effects were significant alone ($p \geq 0.805$). At 27 °C, mean calcification rates were reduced 50% from 1.8 ± 0.3 µg mm^{-2} d^{-1} (± SE, n = 11) at pH 8.18, to 1.0 ± 0.1 µg mm^{-2} d^{-1} (± SE, n = 10) at pH 7.80, but this trend was not significant ($p > 0.05$). At 29 °C, the direction of the pH effect on calcification was reversed, with mean rates doubling from 1.0 ± 0.6 µg mm^{-2} d^{-1} (± SE, n = 9) at pH 8.18, to 2.0 ± 0.5 µg mm^{-2} d^{-1} (± SE, n = 11) at pH 7.80, although this trend was also not significant ($p > 0.05$).

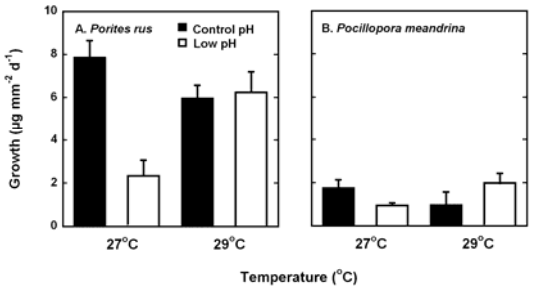

Figure 1. Effect of temperature and pH on the growth (µg mm^{-2} d^{-1}) of (A) *Porites rus,* and (B) *Pocillopora meandrina* during a 14 d incubation under combinations of control pH (8.2) and low pH (7.8); values shown are mean ± SE (n = 9-11 for each temperature and pH combination). Calcification was affected significantly by an interaction between temperature and pH in *P. rus* ($p < 0.001$) and *P. meandrina* ($p = 0.034$), largely because it was depressed by low pH at 27 °C, but not 29 °C.

Maximum dark-adapted quantum yield

The mean F_v/F_m values for all corals before treatment for *Porites rus* (0.573 ± 0.005, mean ± SE) and *Pocillopora meandrina* (0.631± 0.004, mean ± SE) were not significantly different ($p > 0.05$) from the average values in the control tanks after treatment (0.585 ± 0.012 and 0.640 ± 0.011, respectively, mean ± SE, Fig. 2), nor were any treatment combinations of temperature and pH significantly different from each other ($p > 0.05$). For *P. rus*, F_v/F_m was unaffected by pH ($F = 0.971$, df = 1,40, $p = 0.330$), and temperature ($F = 0.428$, df = 1,40, $p = 0.516$), and there was no interaction between the two ($F = 0.587$, df = 1,40, $p = 0.447$). A similar result was obtained for *P. meandrina,* with F_v/F_m again unaffected by pH ($F = 0.022$, df = 1,38, $p = 0.881$), temperature ($F = 0.278$, df = 1,38, $p = 0.600$), or the interaction between the two ($F = 1.108$, df = 1,38, $p = 0.299$).

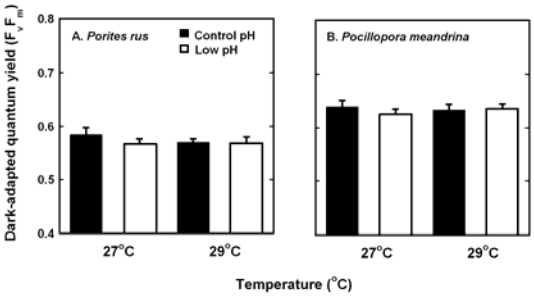

Figure 2. Maximum dark-adapted quantum yield of PSII (F_v/F_m) of (A) *Porites rus,* and (B) *Pocillopora meandrina* incubated for 14 d at control pH (8.2) and low pH (7.8); values shown are means ± SE, n=10-11 nubbins for each treatment combination. For both species, F_v/F_m was unaffected by pH ($p > 0.330$), temperature ($p > 0.516$), and the interaction between the two ($p > 0.299$).

Parameter	Control pH	Treatment pH
pH (NBS)	8.18 ± 0.01	7.80 ± 0.01
Alkalinity (μEquiv kg^{-1})	2143 ± 68	1638 ± 66
pCO_2 (μatm)	395 ± 40	720 ± 205
Total Carbon (μmol kg^{-1})	2010 ± 41	1692 ± 40

Discussion

The effects of high temperature and OA on coral reefs are predicted to compromise calcium carbonate accretion, reduce coral diversity, and weaken the carbonate reef framework (Hoegh-Guldberg 2005). The likelihood of such outcomes is increased by the lack of evidence demonstrating that corals can acclimatize to the effects of OA (Langdon et al. 2000). Nevertheless, there is good reason to suppose that corals exhibit the same kinds of abilities to acclimatize as most eukaryotes (Gates and Edmunds 1999), and for rising temperature there is evidence that some corals can acclimatize to warmer conditions (Jones et al. 2008). Thus while there is a consensus regarding the negative implications for corals of increasing CO_2 and rising temperature (Hoegh-Guldberg et al. 2007), at least when the factors act in isolation, there is less certainty over their interactive effects (Kleypas and Langdon 2006). In order to make accurate predictions of the responses of coral reefs to GCC, experimental manipulations on short time scales are required to understand the potential for interactive effects of CO_2 and temperature.

Utilizing mesocosms, the present study examined the effect of OA on calcification and photosynthesis of *Porites rus* and *Pocillopora meandrina* under two different temperature regimes predicted to occur in the next 100 years (IPCC 2007). An interesting outcome of these analyses is the demonstration that a decrease in pH interacts with small differences in temperature to decrease growth at 27.3 ^{o}C, but not at 29.4 ^{o}C; this effect was striking for *P. rus*, but was less developed in *P. meandrina*. These finding differ from those of Reynaud et al. (2003), who found that the inhibitory effect of elevated CO_2 (760 ppm versus 460 ppm) on the growth of *Stylophora pistillata* were accentuated at higher temperature (28 ºC versus 25 ºC). However, Reynaud et al. (2003) also found no inhibitory effect of high CO_2 at 25 ºC, which is inconsistent with previous studies that have reported inhibitory effects of high CO_2 on coral calcification over a range of temperatures (23 - 27 ºC) (Kleypas and Langdon 2006). However, Langdon and Atkinson (2005) reported findings that are similar to the present study, principally by showing indirectly that higher temperature may alleviate the effects of increased CO_2 on coral calcification. Importantly, they found that a reduction in pH of 0.22-0.28 depressed the calcification of *Montipora capitata* and *Porites compressa* by ≈80% during the cool winter, but by only ≈40% in the warm summer, although the net effect of temperature on the relationship between Ω_a and calcification was not significant (Langdon and Atkinson 2005). The present findings could have biological significance as they suggest that elevated temperature can mitigate the effects of rising CO_2, at least for some corals over a short period.

In the context of evaluating how temperature might alleviate the effects of high CO_2 on coral calcification, it is noteworthy that temperature has numerous biological effects that operate in a biphasic pattern, with rising temperature stimulating processes to a threshold value, and inhibiting them beyond this point. For corals, rising temperatures stimulate enzyme activity (Marshall and Clode 2004) and metabolic rate (Edmunds 2005), and drives the classic bell-shaped relationship between calcification and this physical factor (Marshall and Clode 2004) with typical threshold temperatures of 26-28 ºC (Buddemeier and Kinzie 1976). Together, these results suggest that the temperature manipulations used in this study might not have surpassed the threshold value for calcification in *Porites rus* and *Pocillopora meandrina* in the warm lagoon of Moorea, perhaps because acclimatization to local conditions (Jones et al. 2008) has lead to higher threshold temperatures in this location. With a high threshold temperature for calcification (e.g., > 29 ºC), the effects of the temperature increase in the present study may have been sufficient to offset the effects of carbonate limitation caused by low pH, at least temporarily.

The lack of a significant effect of temperature and pH on F_v/F_m indicates that the high temperature treatment (29 ºC) in this experiment did not reduce photosynthetic efficiency in photosystem II (PSII) when compared to the control temperature treatment (27 ºC). Although temperatures above 29 ºC can reduce photosynthesis in hermatypic corals (Coles and Jokiel 1977), there is considerable evidence demonstrating that the severity of thermal stress is best measured by its magnitude relative to the local seasonal maximum temperature (Jones et al. 2008), with increases of 1 to 2 ºC above this value typically serving as reliable predictors of photosynthetic damage (Hoegh-Guldberg et al. 2007). In the lagoon of Moorea, the maximum temperature recorded at the site of collection is 29-30 ºC, and therefore the high temperature used in the present study may have been too low to illicit a negative response in photosynthesis in *P. rus* and *P. meandrina*. In this context, the

absence of a pH effect might be construed as preliminary evidence that more acidic conditions do not enhance the sensitivity of F_v/F_m to high temperature.

Abstract. Using satellite remote sensing, it is possible to scale-up *in situ* carbonate production observations on coral reefs from habitat (10^{-1}-10^{0} km^2) to regional (10^{3}-10^{4} km^2) scales. Using a time series of Landsats 5 TM and 7 ETM+ spanning 18 years from 1984-2002 with 30 m spatial resolution, it is possible to quantify changes in the spatial extent of reef habitats in the Florida Keys. This study focused on the shallow (<6 m) backreefs, reef flats, and forereefs along the length of the Florida Keys. Twenty-eight georectified images were subjected to atmospheric and water-column corrections, then calibrated for change detection analyses. Published values for production were applied additively to estimate overall changes in production. A reduction in cover of coral habitat of >50% is observed both *in situ* and by satellite data over this time, and is reflected in an estimated decline in production of ~39%. Similar approaches could be applied over other areas with good temporal availability of remote sensing imagery validated by *in situ* observations. Using remote sensing as a tool for scaling-up *in situ* measurements of production has potential applications for modeling synoptic scale environmental impacts, such as the broad reaching effects from ocean acidification.

Key words: remote sensing, ocean acidification, carbonate, Landsat, change detection.

Introduction

Mounting evidence suggests that global climate change, including ocean acidification, will have negative impacts on marine calcifiers, especially coral reef ecosystems (Smith and Buddemeier 1992; Kleypas et al. 2001; Walther et al. 2002; Hughes et al. 2003; Kleypas et al. 2006; Kuffner et al. 2007). Increases in atmospheric and oceanic partial pressure of carbon dioxide (pCO_2) drive changes in the carbonate chemistry of surface ocean waters, decreasing pH and carbonate ion concentration [CO_3^{-2}] (Zeebe and Wolf-Gladrow 2003; Feely et al. 2004). The drop in pH and [CO_3^{-2}] decrease the aragonite ($CaCO_3$) saturation state, making it more difficult for corals to secrete their aragonite skeletons (Gattuso et al. 1998; Kleypas et al. 1999; Gattuso and Buddemeier 2000; Fine and Tchernov 2007).

However, some *in situ* research has indicated that on the scale of reefs or reef biotopes, the net production of carbonate can vary widely (Yates and Halley 2006). Therefore, neither simple geochemical extrapolations, nor single reef-scale metabolic estimates alone can be reliably used to monitor the impact of environmental changes such as ocean acidification on reef processes across time without accounting for changes in reef communities and habitats.

The net metabolism of a given reef zone or biotope can be accounted for by the balance of productivity, or gross photosynthetic carbon fixation (*P*), and respiration (*R*), or their difference, the measure of excess production (*E*) (Kinsey 1985). In addition to carbon metabolism, the amount of carbonate mineral precipitation (*G*) can also be an estimate of reef "health" (Kinsey 1985).

Kinsey (1983) established a linear range of reef metabolic end members, with *P* ranging from 1 g C m^{-2} d^{-1} (100% sand and rubble) to 20 g C m^{-2} d^{-1} (100% coral-algal hard substrate). Calcification also had a linear relationship to the same end members with *G* ranging (respectively) from 0.5 g $CaCO_3$ m^{-2} d^{-1} to 10 g $CaCO_3$ m^{-2} d^{-1} (Kinsey 1983). These metabolic parameters are assumed to have additive properties when scaling-up with remote sensing (Atkinson and Grigg 1984; Andréfouët and Payri 2001).

Despite the general agreement on reefs as sources of CO_2, there is evidence that certain reefs, or parts of reefs, are sinks for atmospheric CO_2 (Kayanne et al. 1995; Ikeda et al. 1997; Yates and Halley 2006). Additionally, recent direct measurements on Moloka'i (Hawai'i, USA) indicate that a reef may operate simultaneously as both a source and a sink in patchy patterns related to biotope spatial distribution (Yates and Halley 2006). This habitat-scale spatial variability of CO_2 production across reefs reflects similar patchiness in carbonate precipitation.

Here we: (1) demonstrate the potential of a time series of Landsat imagery to estimate changes in reef carbonate production over large areas, and (2) report that Landsat based estimates indicate a ~39% reduction in carbonate production across the scope of the Florida Keys since 1984. These results provide important estimates of carbonate precipitation and ecosystem functioning over spatial and time scales that are relevant to ecosystem based management and models of regional responses to ocean acidification.

Material and Methods

Location

The Florida Keys are a chain of low islands extending nearly 400 km from the southeastern tip of Florida to the south and west forming the seaward margin of Florida Bay. In the Keys, the basic zonation proceeds seaward from the islands with a broad, shallow seagrass flat, followed by Hawk Channel with seagrass and patch reefs, then shallowing again to the barrier reef complex ~5 km offshore. The Florida Keys have an unfortunately well documented record of decline in reef health in recent decades (Dustan et al. 2001; Gardner et al. 2003; CREMP 2005; Palandro et al. 2008). This study focused on several shallow portions of the barrier reef complex ≤6 m deep, specifically at Carysfort Reef, Grecian Rocks, Molasses Reef, Looe Key Reef, Western Sambo, and Sand Key Reef (Fig. 1). These sites are representative of shallow barrier reefs of the Florida Keys. They were selected in part because each is a Sanctuary Preservation Area within the Florida Keys National Marine Sanctuary, and in part because these sites have been monitored annually by the Coral Reef Evaluation and Monitoring Program (CREMP) since 1996.

Image Classification, Validation, and Interpretation

Eight Landsat 5 TM and four Landsat 7 ETM+ images were used for this study. Both satellite sensors are equipped with three discrete visible spectral bands useful for this study, specifically the blue (450 nm–520 nm), green (520 nm–600 nm) and red (630 nm–690 nm) bands. This study used images acquired in 1984, 1988, 1992, 1996, 2000, and 2002 during the spring season (March–May). Two Landsat scenes were required to cover the Florida Keys Reef Tract (path/row 15/43 and 16/43). The images were resampled at 30 m spatial resolution, georectified, and transformed to at sensor radiance (L) using calibration coefficients provided with each file. Atmospheric and water-column corrections were applied to each image, and images were calibrated for change detection by an empirical line calibration as detailed in Palandro et al. (2008). Detailed image classifications for these sites are also available in Palandro et al (2008).

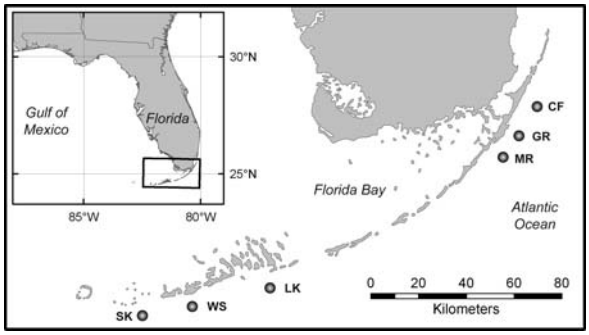

Figure 1. Location map of study sites in the Florida Keys. CF = Carysfort Reef; GR = Grecian Rocks; MR = Molasses Reef; LK = Looe Key Reef; WS = Western Sambo; SK = Sand Key Reef.

From *in situ* observation, four benthic biotopes (i.e., classes) were determined: sand, sparse live substrate, dense live substrate, and coral habitat. Dense live substrate, as measured on Florida patch reefs by Brock et al., (2006), consisted of an average of ~7% live hermatypic coral cover, ~27% macroalgae (calcareous and fleshy), about 10% gorgonians, and 21% bare hardbottom. Sparse live substrate represents areas with the same components as dense live substrate, but with ≥70% bare hardbottom. The sand class is dominated by unconsolidated carbonate sands of varying thickness. The coral habitat biotope represents areas with *in situ* observations of 22% live hermatypic (scleractinian plus hydrocoral) coral cover.

Image classification is based on training pixels determined from *in situ* observations in the same period as the 2002 Landsat images. Image classification was performed using a supervised Mahalanobis Distance classifier with ENVI image software (v4.3). Additional validation of classification was performed by proxy using higher spatial resolution IKONOS imagery, and by *in situ* data compiled from published (Lang 2003; CREMP 2005) and unpublished sources in that time interval.

For this study, the transformed divergence class separability statistic indicated each class was statistically distinct with a mean TD=1.91. Unfortunately, rigorous accuracy assessment is impossible to apply to historical data that were not collected in the context of a remote sensing study with image-driven sampling protocols. In this study,

accuracy assessment of the classification for historical images was performed by generalized comparison to CREMP data.

Carbonate Parameters and Scaling

This project takes advantage of values for reef carbonate production recently reported by Brock et al. (2006) for similar biotopes, but over a smaller area of the North Florida Reef Tract (Tab. 1). The values for *G* were measured with a unique *in situ* mesocosm, the Submersible Habitat for Analyzing Reef Quality (SHARQ) that is operated by the U.S. Geological Survey (Yates and Halley 2003). Brock et al. (2006) presented values for *P*, *R*, *P/R*, *E*, and *G* for three reef biotopes common to our sites: sand, dense live substrate, and sparse live substrate. For this current study, we adopted those biotope definitions and carbonate production values. The coral habitat class value for *G* is calculated here as a linear mix of calcification end members (Kinsey 1983) representing 22% live coral cover (Tab. 1). With no *in situ* SHARQ data available for a class with 22% live coral cover, the Kinsey (1983) end members for *G* offer a suitable basis for interpolation.

Table 1. Values used for estimation of carbonate production. * = directly from Brock et al. (2006).

Class	*G* (g $CaCO_3$ m^{-2} d^{-1})
Sand*	0.11
Sparse Live Substrate*	-0.04
Dense Live Substrate*	1.29
Coral Habitat	2.64

Carbonate precipitation on coral reefs is assumed to be an additive process such that the whole is equal to the sum of the parts (Atkinson and Grigg 1984; Hatcher 1997). For example, the contribution of the coral habitat class to the carbonate production (*G*) for the whole of a given reef complex is a function of the relative fractional area (m^2). The total carbonate production for a reef area depends on the sum of the production of the included biotopes (sand, dense live substrate, sparse live substrate, coral habitat). The measured value for *G* (g $CaCO_3$ m^{-2} d^{-1}) for each biotope (Tab. 1) is multiplied by the fractional area covered by that biotope ($F_{biotope}$). It follows as Eqn. 1:

$$G_{reef} = (F_{sand} \times G_{sand}) + (F_{dense\ live} \times G_{dense\ live}) + (F_{sparse\ live} \times G_{sparse\ live}) + (F_{coral\ habitat} \times G_{coral\ habitat}) \quad (1)$$

Two values for G_{reef} were calculated at each time step. The more conservative number was generated by assuming that in 1984, areas classified as coral habitat, consisted of 22% live coral cover like they do today, thus assuming modern levels of production (*G*) as well. However, this is not likely given the known declines in percent coral cover (Gardner et al. 2003; CREMP 2005). Integration of trends from published (Dustan 1985; CREMP 2005) and unpublished data for these sites produced a simple model of hindcast percent live coral cover at each site during each time interval. The model was based a linear extension of trends from CREMP data (CREMP 2005) at each of the sites, validated where possible by comparison with observations of coral cover during the 1980's. The hindcast live coral cover values in 1984 ranged from 38%-56% which was reflected in corresponding hindcast estimates of carbonate production (G_H).

Results

Validation of the benthic biotopes demonstrated that classification of the most recent (2002) Landsat images was 86% (±2%) accurate across the six reefs in this study, similar to results over much broader regions of the North Florida Reef Tract (Moses et al. in press). Sand has a broad spectral signature, leading to the most frequent misclassification of these four biotopes, typically misclassified as sparse live substrate. However, misclassification of sand as sparse live substrate has a relatively small impact on estimates of G_{reef} compared to changes in percentage of coral habitat, due to the relatively small values of *G* in those biotopes.

The decline of coral habitat correlates significantly (r^2 = 0.71, N = 32) with the decline in percent live coral reported by CREMP. It is important to point out that the decline measured by the 30 m Landsat pixels is decline in the area of coral habitat (a biotope that averages 22% live cover), and is not the same as the decline in percent coral cover as detected by CREMP. However, the two measures are directly related (Palandro et al. 2003; Palandro et al. 2008).

The mean conservative change in carbonate production (ΔG) between 1984-2002 over the six reefs was -20% (±22%). Without hindcast adjustment, Sand Key Reef even appears to slightly increase *G* over the study period. The mean hindcast ΔG_H suggests a greater decline of -39% (±14%) (Fig. 2). The more realistic hindcast values ranged from ΔG_H = -15% at Sand Key Reef to ΔG_H = -57% at Western Sambo.

During the period from 1996-2002, all sites suffered a steady decrease in the coral habitat biotope. Despite this, four of the six sites actually suggest slight increases in carbonate production in the 2000 or 2002 estimates. In the case at Grecian Rocks between 1996-2002, area percent of coral habitat biotope decreased from 21.7% to 14.0%, yet carbonate production increased from 1.13 to 1.20 g $CaCO_3$ m^{-2} d^{-1}.

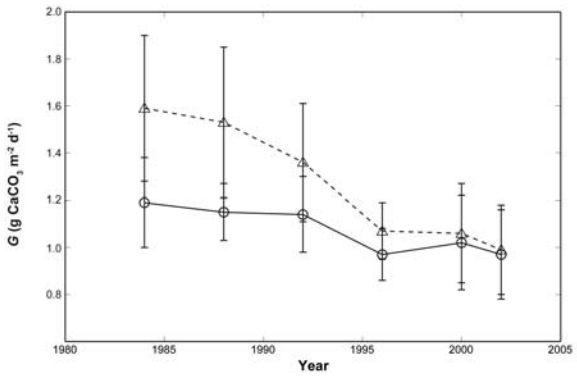

Figure 2. Average satellite estimated decline in carbonate production in the Florida Keys. Solid line with circles represents estimations based on a consistent 22% live cover (G). Dashed line with triangles represents estimates based on hindcast live coral cover (G_H).

Discussion

Work presented here suggests substantial declines in carbonate production on reefs in the Florida Keys. The roughly 40% decline in carbonate production over about two decades, an average rate of decrease of ~2% per year, implies a substantial limitation from broad reaching factors on reef accumulation in the Florida Keys.

The observed increases in G estimated for 2000 and 2002 for some sites are likely an ecological recovery in response to the 1998 bleaching event. The 1998 bleaching event reduced the actual percent live coral cover (CREMP 2005), transforming coral habitat area to sparse live substrate. Subsequent recovery of the sparse live substrate to dense live substrate increased the carbonate production, but not the area coverage of coral habitat, which continued to decline. Unfortunately, trends of live hermatypic coral cover on Florida reefs continue to suffer under substantial stressors (Maliao et al. 2008), making recovery of dense live substrate to coral habitat seem unlikely.

These results do not specifically confirm direct influence of ocean acidification on carbonate production and reef accretion in the study area. However, the results describe the magnitude and geographic scope of decline in carbonate mineral precipitation in the Florida Keys, which likely stems from a combination of antagonistic environmental factors operating across a range of scales (Gardner et al. 2003; CREMP 2005).

Models like this have the potential to be accurately applied over regions with good *in situ* habitat cover data as well as carbonate production observations. The additive model reported here does not account for complexities such as sea surface temperature or water retention time. However, improved estimates can be made by incorporating more environmental data that could influence the calculations of G. Inclusion of such components would result in a gradient of carbonate production values in each model grid cell (i.e., Landsat pixel). This would be more realistic than the current list of discrete values for G. Additional *in situ* data collection, with systems like the SHARQ, will provide more control points for benthic community production of carbonate, especially if measurements are expanded into deeper waters of previously unsampled geographic areas.

Fine banding in the septa of corals.

I. M. Sandeman

Dept of Biology, Trent University, 1600 West Bank Drive, Peterborough, Ont. Canada K9J 7B8

Abstract. Fine banding is apparent in the crystalline areas of thin ground and polished sections of coral septa when viewed with phase contrast optics. In some septa (e.g. *Meandrina meandrites*) the banding is robust and a series of laminations representing several months of growth can be followed. Repeated staining with alizarin of small colonies of *Agaricia* confirmed that the bands are diurnal and indicated that the darker bands (optically more dense) are formed during the day and the lighter bands at night. Ground and stained sections of *A. agaricites* mounted in epoxy resin showed, particularly in the calicoblastic layer areas with high calcification, many bunches of spherical bodies (Golgi apparatus?). These are probably involved in the secretion of the skeletal matrix. Evidence is presented that the Ca^{2+}ATPase pump may be light sensitive and leakage of Ca^{2+} due to lipid peroxidation of the plasma membranes during the day accounts for the higher calcification rates in light. A model of calcification is presented suggesting a mechanism by which the diurnal banding is produced.

Key words: Coral calcification, light, diurnal banding, Ca^{2+}ATPase pump

Introduction

Fine banding in coral skeletons has been studied with a variety of techniques (Risk and Pearce 1992; Perrin 2003; Gill et al 2006). Daily or circadian banding has been reported in the epitheca of corals but is of limited use in environmental studies (Risk and Pearce 1992). Some microbands appear to be the result of secondary skeletonization processes or later infilling of pore spaces between the theca. (Gill et al 2006). Septa, however, have received little attention. They can be easily removed from live corals and, if fine banding is present and can be confirmed as diurnal, septa have the potential to provide a record of recent environmental events on a daily time scale. In addition to providing growth rate information there is the potential of providing chemical proxies which can be related to environmental variables in the form of trace elements and stable isotopes using laser ablation techniques. The aim in this study was to determine whether coral septa have fine diurnal bands and explore how light may be involved in their formation.

Materials and methods

All sea water used for experiments was passed through a column of 4-8 mesh activated charcoal (Sigma) and millepore-filtered (0.45µ). Small pieces of live coral were collected in the back reef at Discovery Bay, Jamaica and were held in the sea water table at the Discovery Bay Marine Laboratory of the University of the West Indies. Small platelike colonies of *Agaricia agaricites* with a thin outer edge proved to be a particularly useful source of material as the structure was simple, consisting of parallel septa, without polyps. Pieces could be easily trimmed to a desired shape with small scissors.

For alizarin staining small colonies of Agaricia were collected from the back reef and at 0900 hrs placed in a large clear plastic bag with 20mg/l of alizarin red. The colonies were removed at 1800 hrs to the water table where they were held in running sea water. Four days later they were again placed in sea water with stain, at midday, and returned to the water table at 1800 hrs. Forty eight hours later the corals were water-piked clean and dried.

Small pieces of *Agaricia* were fixed in modified Karnovsky solution (2.5% glutaraldehyde, 2% paraformaldehyde in 0.1 M Sorenson buffer), dehydrated, embedded in LR White (hard) acrylic resin (Sigma) and cured at 60ºC under nitrogen. Slices were cut with a diamond saw. The slices, mounted on glass slides with thermoplastic cement, were ground with a series of microabrasive sheets to a thickness of less than 0.05 mm. The sections were then ground and polished on one side, heated, detached and turned over. After re-attachment they were ground and polished on the second side and stained with toluidine blue. After washing in distilled water and drying the sections each received a drop of immersion oil and a cover glass.

Septa were carefully removed, oriented and mounted on glass slides with thermoplastic cement (Crystal Bond). For cross sections larger septa were first sectioned with a diamond saw, ground with a series of microabrasive sheets, polished on one side,

detached on a hot plate, turned over, reattached and ground and polished on the other side. Progress was monitored regularly under a microscope (Wild M20 provided with phase contrast optics) and turned over several times during grinding to ensure that the final result was a section through the centre of a trabecula. Photographs were taken with an Epson PC800 digital camera.

The acetoxymethyl (AM) ester of the cell permeant calcium indicator calcium orange (Molecular Probes Inc.) is permeable to living cells. On entry it is hydrolysed to release the fluorescent calcium indicator in a charged form that is less permeant to cell membranes. 50 µg of calcium orange was dissolved in 0.1ml of a 20% solution of Pluronic® F-127 in dimethyl sulfoxide (DMSO). This was added to 20 ml of sea water to give a 4 µM working solution. Small pieces from the edge of thin plates of *Agaricia agaricites* were incubated for 30 min, rinsed in sea water, trimmed and placed with 0.6 ml sea water in a sample vial in the fluorometer (Sandeman 2006). The sample vial was a 9x30 mm Kimble glass vial with a neoprene 0-ring round the top and the bottom was shielded with a disc of black electrical tape. Excitation at 532 nm was provided by a green laser diode module (E1894, Egismos Technology Corporation). The beam was spread by a double concave lens in its path. Fluorescence (peak at 575-580 nm) collected by the ellipsoidal mirror is passed through a broadband interference filter (560-640 nm, Edmund Optics, A46-159) to the 2.0x2.0 cm blue enhanced silicon photodiode, PerkinsElmer Optoelectronics, at the second conjugate focus of the mirror. In the lamp housing three miniature blue light emitting diodes (LEDs, Maplin Electronics, N31AT) arranged round the excitation beam provided continuous illumination to the sample. The LEDs were independently switched and each provided approximately 100 µmol.m-2.s-1 at the bottom of the sample vial as measured with a LI-COR Quantum Radiometer (Model LI-250). The supply voltages for the laser diode and LEDs were regulated. For fluorescence readings the laser was switched on for as short a time as possible. Fluorescence usually decreased briefly after being switched on but quickly stabilized. Preliminary experiments indicated that photo-bleaching did not occur and fluorescence from coral or algal pigments did not interfere with the signal from the intracellular calcium. There was only slight leakage of the calcium probe.

Results

Of the species investigated *Meandrina meandrites* had robust easily seen banding (Fig. 1a-b). Each septum consistes of a palisade of parallel trabeculae with sclerodermites, or whorls of fibres, radiating out from growth centres. In longitudinal section the banding is continuous across two or more trabeculae (Fig. 2b). In vertical sections (Fig. 2a) the series of bands

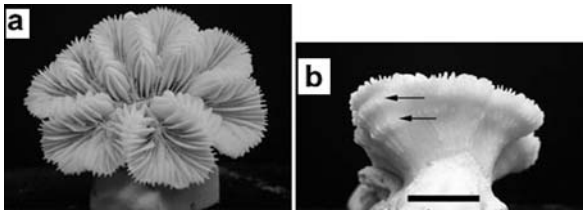

Figure 1a-b: Skeleton of colony of *Meandrina meandrites*, scale bar 1 cm. a septa. b epitheca with summer growth ridges(arrows).

can be followed for a considerable distance and the variation in the separation of the bands is considerable (4-15µ).

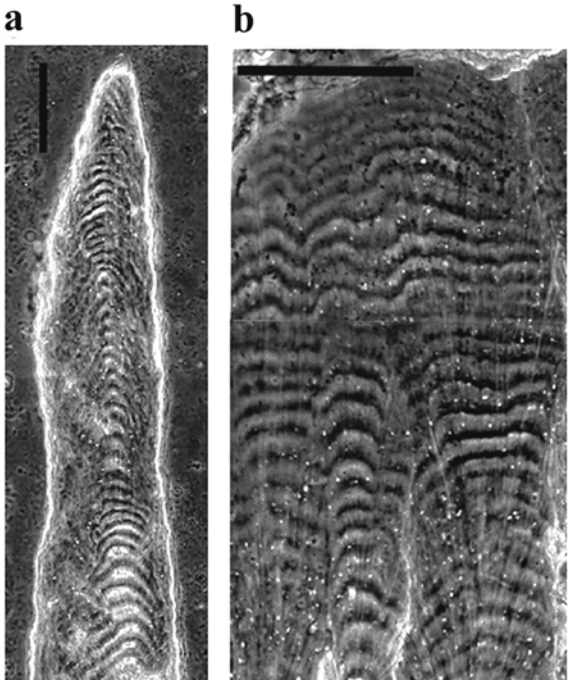

Figure 2a-b: Ground and polished thin sections of septa from *Meandrina meandrites* viewed with phase contrast optics, Scale Bar 100µm. a Vertical section, b Longitudinal section.

A similar arrangement of the trabeculae and banding was seen in several other coral species investigated: Dendrogyra cylindricus, *Dichocoena stokesii* and *Eusmilia fastigiata*. In *Montastrea annularis* (Fig. 3a) the trabeculae and pattern of banding were only visible in patches and sometimes obscured by whorls of radiating fibres or sclerodermites. In *Siderastrea siderea* central strips of crystalline banding were surrounded by amorphous material (Fig. 3b) In some species, especially those with thicker septa, eg *Dendrogyra cylindricus*, the trabeculae are not parallel and have a three dimensional fanlike arrangement

which makes the banding more difficult to follow. Some of the faster growing shallow water corals examined, *Acropora cervicornis, Siderastrea radians* and *Porites porites* appeared to have few crystalline areas with visible banding and most of the skeleton appeared to be deposited in an amorphous form.

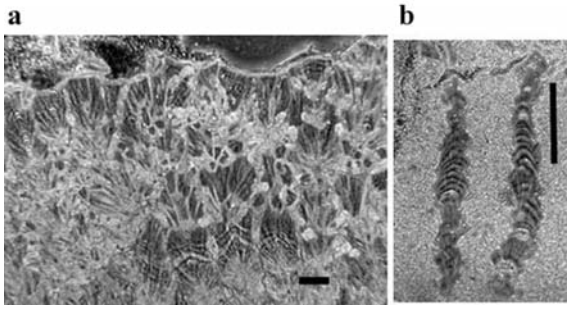

Figure 3a-b: Ground and polished thin sections of septa viewed with phase contrast optics, Scale bar 50µ. a *Montastrea annularis*. b *Siderastrea siderea***.**

The epitheca (Fig. 1b) of the colony of *Meandrina meandrites* from which the septa shown in Fig. 2 were taken had annual protruding ridges 4 mm apart. This translates into an average daily growth rate of 11µ which fits well with the separation of the laminations of the septa. Sections from the small colony of *Agaricia agaricites* which had been stained twice with alizarin four days apart (Fig. 4) confirmed that the laminations are diurnal and indicated that calcium was laid down during the day in the darker bands.

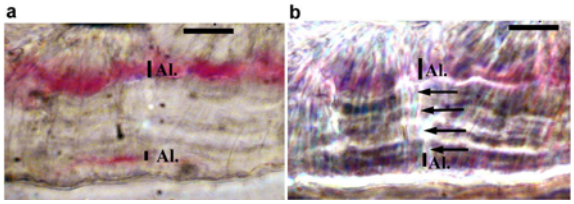

Fig. 4**:** Ground and polished sections of a septum of ***Agaricia agaricites*** after double staining. Scale bar 10µ. Al indicates stained layers, arrows dark bands. a standard optics. b phase contrast.

The two layers lining the skeleton of *Agaricia agaricites* can be distinguished in section (Fig.5). Zooxanthellae were not seen in the inner endodermal layer and both layers contain many clumps of vesicles that stain with toluidine blue indicating that they probably contain protein. These clumps of vesicles were profuse where calcification, as judged by the take-up of alizarin by the skeleton, was strongest, particularly on the septa. The stained vesicles were not seen in other tissues and it seems likely from their position and the quantity of material they contain that the vesicles could be the source of the organic matrix.

Fluorescence levels from pieces of *Agaricia* loaded with calcium orange leveled off within 10-15 minutes (Fig.6). The variation in fluorescence levels between different pieces of ***Ag****aricia* was high and depended on the extent to which the fluorescent probe was taken up by the coral pieces. When illuminated continuously with blue light from one or more LEDs the fluorescence level dropped quickly and adjusted to a new level. When the LEDs were switched off fluorescence returned slowly to close to its original level.

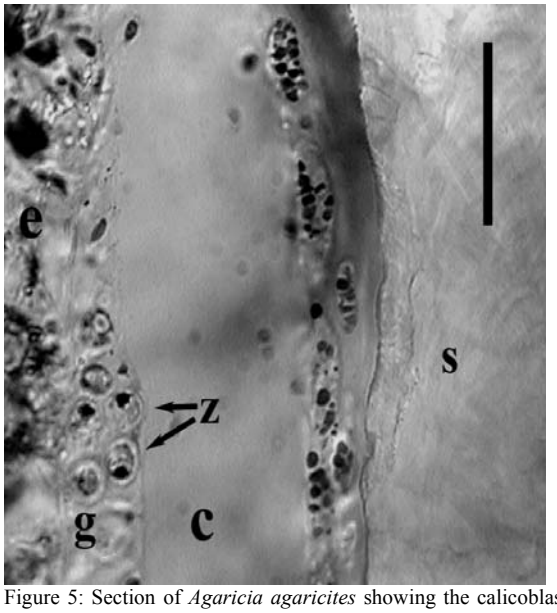

Figure 5: Section of *Agaricia agaricites* showing the calicoblastic endodermal and ectodermal layers, detached from the septal wall, with cells with stained secretory vesicles. **c** coelenteron, **e** epidermis, **g** gastrodermis, **s** septum, **z** zooxanthellae, Scale bar 50 µm.

Fig. 6 shows a typical result obtained using the same piece of *Agaricia* exposed to three different light levels with a dark period. As can be seen the change in fluorescence was proportional to the light intensity. With two LEDs switched on (200µmols.m^{-2}.s^{-1}) the fluorescence dropped to a new mean level 33.5 % lower than the original level (n=7).

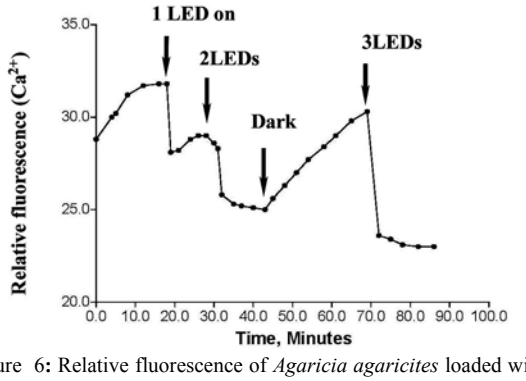

Figure 6**:** Relative fluorescence of *Agaricia agaricites* loaded with the intracellular fluorescent probe calcium orange. The relative change of fluorescence with time is shown for changes in light level (each blue LED emits 100 µmol.m-2.s-1).

Discussion

Comparison of the average separation of the bands of *Meandrina meandrites* (Fig. 2) with the annual ridges on the epitheca (Fig. 1b) and the sequential alizarin

staining of *Agaricia agaricites* (Fig. 4) indicated that the banding is diurnal. From the septa of the corals examined it is clear that a few species have the potential to provide a useful daily record of growth over periods of several months. These are generally species in with large, thin septa with robust banding in which the trabeculae are parallel and growth takes place in a single plane, eg *Meandrina meandrites*, *Fungia* sp. and *Eusmilia fastigiata*. In species such as *Dendrogyra cylindricus* with thick septa, many trabeculae grow at an angle to the main axis and these thicken the septae. However, this makes it difficult to find and follow the main growth axis. In other species the banding is either too patchy to follow or there are deposits of amorphous material with little or no banding visible. Variation in the separation of the bands in the septae of *Meandrina* was from 4-15 μ and bands can be counted up to the surface so that the exact date of variations can be pinpointed accurately.

Cohen and McConnaughey (2003) suggested that the role of the vesicles in the calicoblastic epithelium was the transport of seawater into the calcifying space. The clumps of vesicles seen in the two layers lining the skeleton in this study look like Golgi bodies which are often associated with the secretion of glycoproteins. The vesicles take up stain and are therefore unlikely to contain seawater and are interpreted here as the probable source of the organic matrix. The volume occupied by the vesicles (Fig. 5) appears to be enough to provide the 3-4 μ layer that would be laid down daily. No zooxanthellae were seen in the inner 'endodermal' layer and the two layers appeared very similar and vesicles were present equally in both layers, indicating that both layers may be involved in skeletogenesis. Physical extension of the coral takes place at night (Vago et al 1997) and this is presumably when the organic matrix is secreted. The role of the matrix is reviewed by Cohen and McConnaughy (2003). The matrix has been shown by Tambutté *et al* (2007) to consist of structural proteins which also play a catalytic role similar to that of carbonic anhydrase. It has also been shown to have calcium binding properties (Isa and Okazaki 1987; Constantz and Weiner 1988; Puverel et al. 2005). The dynamics of the synthesis and deposition of the organic matrix is not well known (Allemand et al, 1998) but its production may be the determining factor for calcium deposition rather than Ca^{2+} (Wainwright, 1963; Allemand et al 1998). The observation that the concentration of vesicles is highest in the areas of the coral where growth is highest may confirm this view.

Corals, like other organisms, maintain low intracellular Ca^{2+} levels (Barnes and Chalker 1990; Al-Horani et al, 2003) and failure of the Ca^{2+}ATPase pump at high temperatures was involved in 'dark' bleaching (Sandeman 2006). 'Solar' bleaching involved build-up of H_2O_2 produced in photosynthesis. H_2O_2 at lower levels may also play a role in the regulation of algal density (Sandeman 2006). It is also evident, from the stable isotope fractionation of calcium (Gussone et al 2005; Bohm et al 2006), that the Ca^{2+}ATPase pump is involved in transporting Ca^{2+} into the extracellular calcifying fluid (ECF) where it is deposited. Many mechanisms have been invoked to explain the significantly higher calcification rates of corals in light than in the dark, these were reviewed by Gattuso et al (1999). More recently Al-Horani et al (2003), using Ca^{2+} microsensors found that the Ca^{2+} concentration under the calicoblastic layer of *Galaxea fascicularis* increased in the light and when the light was switched off the Ca^{2+} decreased. This was interpreted as calcium transport to the skeleton site being triggered by light with the additional ATP needed being supply from photosynthetically driven respiration. Cohen and McConnaughy (2003) proposed a model of calcification based on this light-sensitive action of the Ca^{2+}ATPase pump. The experiments undertaken in this study with *Agaricia agaricites* loaded with the fluorescent intracellular calcium probe indicated that the intracellular Ca^{2+} concentration decreases rapidly by 33% in light (200 μmol photons m^2. s^{-1}). The decrease was more or less proportional to the light intensity. In the dark the Ca^{2+} concentration returned slowly to its previous level. These results are interpreted as confirmation that the Ca^{2+}ATPase pump is light sensitive. However increased activity of the Ca^{2+}ATPase pump in the light does not explain how Ca^{2+}, which because of its charge is unable to move passively through the plasma membrane, gets into the calicoblastic layer in the first place from the large pool (Goreau 1959) in the coelenteron. Mechanisms involving special channels (Zoccola et al 1999; Clode and Marshall 2002) or special cells (Tambutté et al 1996) or transport of seawater by pericellular pathways or vesicles (see Cohen and McConnaughey 2003) have been suggested. Sandeman (2008) showed that lipid peroxidation in *Agaricia agaricites* in light (800μ mol photons) increased to a maximum in about four hours then reduced back to its original level. Lipid peroxidation, produced as a result of build up of H_2O_2 is known to make membranes leaky to Ca^{2+} (Halliwell and Gutteridge 1999) and it was suggested that the leakage provides a route for additional Ca^{2+} and other ions to enter cells of the calicoblastic layer. In that study the build-up of lipid-peroxidation parallels, almost exactly, the way that calcification rates of *Galaxea fascicularis* in light (200 μmol photons) measured by al-Horani (2007) increased to a maximum in six hours then decreased again. The difference in timing can be attributed to difference in light levels. Lipid peroxidation levels at the beginning of experi-

ments (Sandeman 2008), before exposure to light, and at the end of experiments were about 50% of the highest levels in light. This indicates that there may be a constant level of lipid peroxidation even in the dark and continuous leakage of Ca^{2+} and other ions into the tissues accompanied by a low level of Ca^{2+}ATPase pump activity. In light the activity of the Ca^{2+} pump increases and this may explain the higher calcification rate in light for ahermatypic corals. Zooxanthellate corals would experience even higher rates of calcification during the day as a result H_2O_2 build-up, increased lipid-peroxidation and leakage of more Ca^{2+} into the calicoblastic layer. The results and elements of the above discussion are combined into a model, following Adkins et al (2003), presented in Figure. 7.

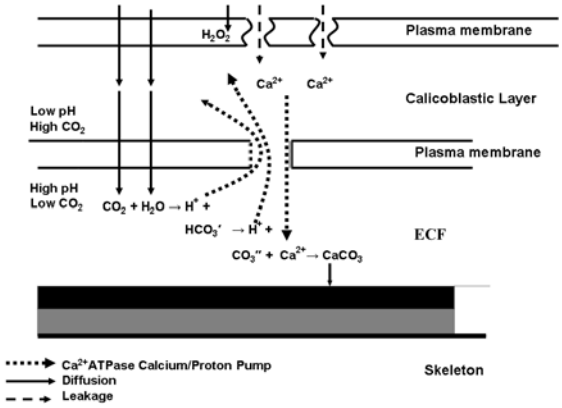

Figure 7: A calcification model for diurnal banding. Low levels of intracellular Ca^{2+} are maintained by the Ca^{2+}ATPase/proton pump which is light sensitive and maintains a lower level of Ca^{2+} in light. H_2O_2 produced by zooxanthellae builds up during the day, causes lipid peroxidation of the plasma membrane, makes it leaky to Ca^{2+} and provides a route for more Ca^{2+} (and other ions) to enter the calicoblastic layer. Secretion by the calicoblastic layers of a new layer of organic matrix takes place during the night. It has Ca^{2+} binding and enzymatic properties which enhance adhesion and the formation and deposition of $CaCO_3$. Ca^{2+} is actively transported into the ECF by the Ca^{2+}ATPase pump and protons are transported in the opposite direction. The removal of protons enhances the formation and deposition of $CaCO_3$ and the pH changes enhance the diffusion of CO_2 into the ECF. There is greater deposition on the new layer of the organic matrix during the day. This results in alternating low and high density laminations.

Abstract. The variation in the Sr/Ca ratio of coral skeletons is sensitive to changes in temperature and presents an archive for reconstructing the paleo-seawater environment. Information on the mineral phases corresponding to coral skeletal textures from micro- to nano-meter scales would be helpful toward resolving the mechanism causing the variation of Sr/Ca ratio. To confirm mineral phase differences in coral skeletons, we conducted the mineral phase identification in microstructures and nano-textures of the coral *Porites lobata* by X-ray diffraction analysis with synchrotron radiation (SR-XRD) and transmission electron microscope (TEM), respectively. Coral skeletal microstructures consist of centers of calcification (COC) and fibers. COCs are < 30 μm in diameter in the samples. The X-ray beam size of SR-XRD collimated of 15 μm and 40 μm in diameter enabled us to obtain the information of mineral phase in COCs and fibers separately. All diffraction peaks of COCs and fibers can be explained as aragonite with the lower detection limit of ca. 0.5 wt% of strontianite by SR-XRD. All TEM observations also indicate the aragonite phase in coral skeletal nano-textures.

Key words: Mineral phase, SR-XRD, Coral, Skeleton, Microstructures

Introduction

The strontium/calcium (Sr/Ca) ratio in coral skeletons varies with surrounding temperature change has and thus may provide an accurate paleo-thermometer of sea surface temperature (SST) (de Villiers et al., 1995). Coral skeletons are reportedly composed of only aragonite so that the Sr heterogeneity derives from the compositional rates of solid solution of aragonite.

Greegor et al. (1997) reported that as much as 40% of strontium (Sr) in coral aragonite existed as strontianite ($SrCO_3$) by using X-ray absorption near-edge structure (XANES) and extended X-ray absorption fine structure (EXAFS). The presence of strontianite in coral skeletons could significantly influence Sr/Ca paleo-thermometry because the thermometry assumes the strontium in coral aragonite exists in solid solution. Greegor et al. (1997) implied that Sr did not substitute simply for Ca, and therefore coral Sr/Ca thermometry could not be applied for paleo-environmental analysis. Indeed, coral skeletons contain higher amount of Sr than expected by the solubility limits calculated from synthetic aragonite (Plummer and Busenberg, 1987). On the other hand, EXAFS analyses performed by Finch et al. (2003a, 2003b) and Allison et al. (2005) showed no evidence of the presence of strontianite or its intermediate state in coral aragonite. However, neither XANES nor EXAFS can identify the mineral phase directly.

Recent advances of micro analytical methods allow the analysis of trace elements within the coral skeletal micrometer scale structures (microstructures) that correspond to daily growth resolution (Meibom et al. 2008). Cohen et al. (2001) focused on the substantial heterogeneity of Sr/Ca components in coral skeletal microstructures, which were not solely temperature related. Previous studies explained this heterogeneity as resulting from biological effects, kinetic effects, and different mineral phases. However, no model has yet been generated to explain the effects of biological, kinetics and mineral phases on the observed chemical and isotopic variations. Identification of the mineral of the coral skeletal microstructure and nano-meter scale structures (nano-textures) are thus crucial for explaining these effects.

Few studies on the mineral phase in coral skeletal microstructures have been performed (Vongsavat et al. 2006, Stolarski et al. 2007, Przenislo et al. 2008). Stolarski et al. (2007) were the first to report the mineral phase of coral skeletons, extracted as *en bloc* without pulverization, by high-resolution synchrotron radiation diffraction. However, their study did not analyze the mineral phase corresponding to coral skeletal microstructures.

Here we report the mineral phase identification in coral skeletal microstructures and nano-textures using X-ray diffraction analysis with synchrotron radiation (SR-XRD) and transmission electron microscope (TEM). Microstructures of coral skeletons consist of two morphology; COC (centers of calcification) and fibers (fasciculi) (Partz, 1882; Ogilvie, 1886). The SR-XRD analysis method enables one to identify the

mineral phase of COC and fibers by X-ray spots, 15 μm and 40 μm respectively. Our study provides the first analysis of the mineral phase in coral skeletal microstructures and nano-textures.

Material and Methods

All data were obtained from the scleractinian coral *Porites lobata* collected from Ishigaki Island, Okinawa prefecture, Japan in 2005. The coral samples were prepared by first removing the tissue layers with water and allowing to dry at ambient temperature. Each sample was then cut, rinsed with distilled water and dried at room temperature. Samples were embedded in epoxy resin (Logitech Ltd.) and polished.

Microstructures in the coral skeleton were examined using scanning electron microscopy (SEM) in a section cut vertical to the axis of growth direction on a HITACHI S-3000H at Hokkaido University. Acceleration voltages of the electron beam were 10kV. All samples were polished and etched with 0.5MHCl (5-second), then sputter-coated with a thin layer of platinum.

We performed SR-XRD analysis to identify the mineral phase in coral skeletal microstructures. Before the SR-XRD analysis, we ensured the analysis area was free of micro-holes, then bonded the epoxy resined coral skeletons to the glass slide and polished them < 100 μm thickness. In previous studies, the samples could not be separated from slide because of the thinness of the sample. All the samples have been prepared under the room temperature and were peeled from the glass slides. The experiments were conducted with an imaging plate (IP) on BL-18c at Photon factory, KEK (high energy accelerator research organization), Tsukuba, Japan. A monochromatic incident X-ray beam with a wavelength of 0.616Å was used and collimated to a diameter of 15 μm or 40 μm. These analytical spots were precisely positioned by CCD camera, allowing the spatial distribution in coral microstructures to be directly investigated. The two-dimensional IP data were integrated and conducted to one dimensional intensity data.

Nano-textural observations and diffraction patterns of coral skeletons were performed by Transmission electron microscope (TEM) on JEOL JEM-2010 operated at 200kV. An ultra-thin section of the sample was prepared by finely polishing and Ar ion sputtering. No calcium oxide (CaO) in this analysis indicated that the original mineral phase had been maintained in the coral sample.

In order to verify the detection limit of strontianite in coral aragonite by using SR-XRD, we prepared the synthetic aragonite and strontianite minerals (Kanto chemical co., Inc).

The Sr-free aragonite powder was prepared by precipitation from aqueous solutions (modified from Lucas-Girot *et al*., 2007). A solution of potassium hydrogen carbonate, 0.1 M, was prepared through the dissolution of K_2CO_3 (Wako Pure Chemical Industries, Ltd.) in distilled water. A calcium chloride solution, 0.1M, was prepared by dissolving $CaCl_2 \cdot 2H_2O$ (Kosa Chemical Co., Ltd.) in distilled water. The boiling solution of calcium chloride was added to the stirred boiling solution of potassium hydrogen carbonate. The precipitate was aged 5 min in the boiling mother solution and then filtered, washed with boiling water, and dried 110℃ over night. An XRD pattern showed that powder included aragonite and a little calcite.

We repeated the above cycle, but in the second cycle we added a small amount of aragonite powder, obtained in the first cycle, as seed crystals to the mother solution. The XRD pattern of this powder produced only aragonite peaks.

After the aragonite was synthesized, we intermixed the strontianite to the synthetic aragonite with 0, 0.117, 0.49, 1.26, 3.53, 5.25, 10.10 wt% respectively (see Table.1).

Results and Discussions

Implication for Sr/Ca thermometry

Fig. 1 shows coral microstructures of *Porites lobata* observed by SEM and optical microscope. In this study, the sizes of the COC are about 5-30 μm in diameter. Fig. 2 indicates one-dimensional intensity

Table.1: The amount of strontianite in the synthetic aragonite.

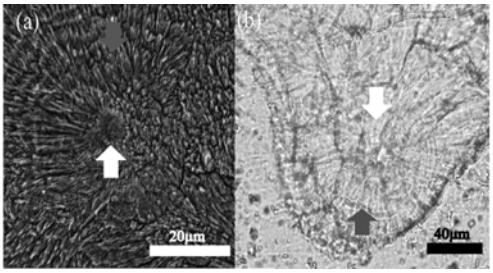

Figure.1: Coral skeletal microstructures of *Porites lobata* in scanning electron microscope (SEM) image (a) and petrographic thin section (b). The white arrow indicates centers of calcification (COC) and the gray arrow shows the emergent bundles of aragonite fibers surrounding the COC. Modified from Sowa *et al*. 2008.

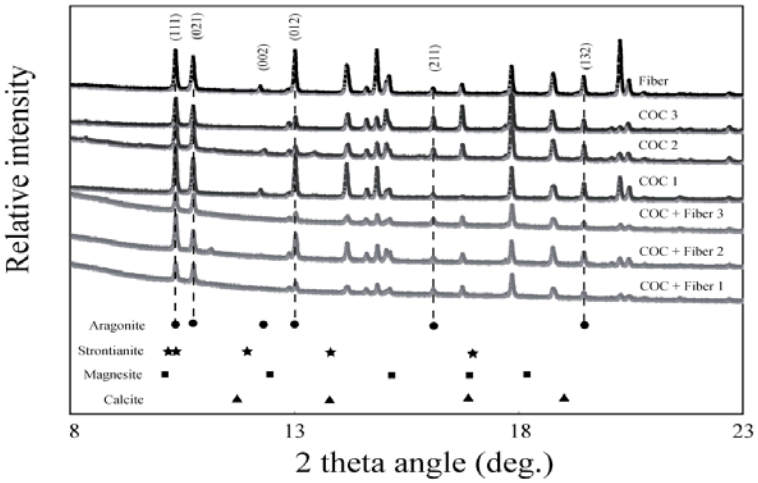

Figure.2: X-ray diffraction patterns of coral skeletal microstructures. Three of diffraction traces were analyzed by 40 μm spot size in diameter (COC + Fiber1-3) and the others by 15 μm (COC 1-3, Fiber). Aragonite, strontianite, magnesite and calcite are represented by solid circle (●), star (★), square (■), and triangle (▲), respectively.

patterns from 8 to 23 degrees 2-theta of the mineral phases in coral skeletal microstructures. The X-ray laser spot sizes of this study are 15 μm and 40 μm respectively, which correspond to the diffraction patterns of COC at three points, fiber of a single point, and an area that includes COC and fibers of three points. These diffraction patterns illustrate that COC and fibers consist only of aragonite.

To examine the mineral phase in coral skeletal nano-textures, we conducted TEM observations in COC and fibers. Coral skeletal nano-textures contain submicron, granular or needle-like shaped grains as shown in Fig. 3. The grain size of coral aragonite by our TEM observation resemble the nano-scale grain size observed by AFM (Cuif and Dauphine 2005). In the coral skeletal nano-textures, we did not find evidence for strontianite in the diffraction patterns of the coral skeletons (Fig. 3).

Fig. 4 illustrates the X-ray diffraction patterns of the six mixture samples of strontianite ($SrCO_3$) and the synthetic aragonite ($CaCO_3$) by SR-XRD. To detect the strontianite by qualitative analysis, we calculated and plotted the relative intensity of strontianite (111) normalized by aragonite (111). The regression line is $Y = 2.83*X$ ($R^2 = 0.96$), which was calculated from samples except 0.117 wt%. The relative intensity of 0.117 wt% was - 0.0673, which was under that of 0 wt%. This experimental result indicates that the lower limit of detection of strontianite in the synthetic aragonite is approximately 0.5 wt%, which corresponds to a Sr content of 2900 ppm (see Table 1). Greegor et al. (1997) reported that 3000 ppm (40 % of 7500 ppm) of Sr presented as strontianite. SR-XRD could detect the strontianite in coral skeletal microstructures if coral skeleton contains 3000 ppm of strontianite.

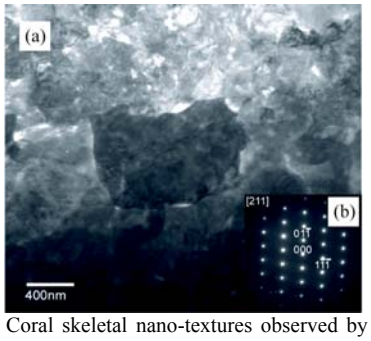

Figure.3: (a) Coral skeletal nano-textures observed by TEM. (b) Electron diffraction pattern of coral aragonite in a selected area.

In our study, however, with lower detection limits of approximately 0.5 wt% of strontianite and without any impurity phase conditions (Fig. 2), diffraction patterns in coral skeletal microstructures present only Bragg peaks at positions corresponding to the aragonite diffraction patterns. We could not detect strontianite and other mineral phase in the coral nano-textures from the diffraction patterns (Fig. 3). Our mineral phase analysis of coral skeletal microstructures and nano-textures are similar to the results of EXAFS and XANES, which showed no existence of strontianite or it's intermediate state in coral skeletons (Finch *et al*., 2003a, 2003b; Allison *et al*., 2005).

Cohen et al. (2001) and Allison et al. (2005) reported that COC contain higher Sr/Ca ratio than fiber. However, there is no significant difference in the mineral phases of COCs and fibers in this study. These results imply that the Sr heterogeneity between COCs and fibers is not due to a difference in mineral phases. The causes of Sr heterogeneity are unclear and the mechanism of biological or kinetic effects remains to be resolved.

In summary, all diffraction patterns of coral skeletal

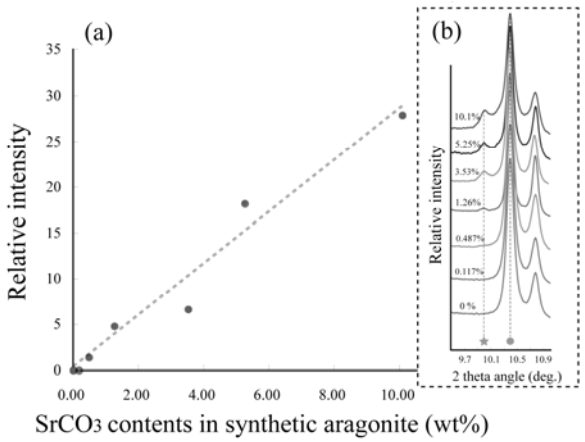

Figure. 4: (a) Experimental detection limit of strontianite ($SrCO_3$) by SR-XRD. Table.1 shows each contents of strontianite. Y-axis indicates that the relative intensity of strontianite (111) normalized by that of the synthetic aragonite (111). (b) The X-ray diffraction patterns of contents of strontianite against the synthetic aragonite; 0, 0.117, 0.49, 1.26, 3.53, 5.25 and 10.10 wt% respectively (see Table.1). Aragonite (111) and strontianite (111) indicate solid circle (●) and star (★) respectively.

microstructures and nano-textures (Figs. 3, 4) indicate that there is no evidence of strontianite in coral skeletons (within the lower limits of detection discussed above) and strontium is likely incorporated into the aragonite as solid solution.

The presence of strontianite remains possible, because our analysis focused only on limited areas in coral microstructures and nano-textures and we did not examine other coral species. Greegor et al. (1997) noted the presence of strontianite in *Montastrea annularis* and *Acropora palmata*. Here we investigated *Porites lobata* because it has been used as a paleo-environmental archive. It is possible that *Montastrea annularis* and *Acropora palmata* contain strontianite in their skeletons. Shirai et al. (2008) reported that Sr is heterogeneous in *Acropora nobillis* skeletal microstructures. Further investigation of the mineral phases of *Acropora* using SR-XRD may be useful.

Mineral phase analysis by SR-XRD and TEM corresponding to the coral skeletal microstructures and nano-textures show solely the aragonite diffraction pattern in this study. These results indicate that Sr/Ca thermometry of coral *Porites* should not consider the presence of strontianite in coral skeletons.

Applications of the SEDCON and FORAM Indices on patch reefs in Biscayne National Park, FL, USA

A. Ramirez, C. Daniels, P. Hallock

College of Marine Science, University of South Florida, 140 7th Ave S, St Petersburg, FL, 33705, USA

Abstract. Coral cover remains highest on patch reefs at the northern end of the Florida reef tract. Two indices, the FORAM Index and the SEDCON Index, were developed to indicate the suitability of a reef environment for continued reef accretion. Patch reefs were sampled in Biscayne National Park, FL, to assess sediment characteristics and foraminiferal assemblages, as well as to examine trends between the two indices. Sediments associated with a majority (59%) of reefs were coarse sands; muddy sediments were restricted to a few inner patch reefs that were isolated from the flow of Caesar's Creek. Unidentifiable grains dominated the sediment constituents, along with calcareous algae and molluscan debris. Shells from 82 genera of Foraminifera were identified in the sediments. *Quinqueloculina* was the most consistently common genus. Percent mud was the most influential measured variable on the distribution of both sediment constituents and foraminiferal assemblages. Patterns of FORAM and SEDCON Index values and their similarity to temperature, salinity, and percent mud distributions show that Caesar's Creek is affecting the benthic community by providing flow that limits the accumulation of mud and potentially other anthropogenic stressors. Overall this study suggests that the reefs in this area are marginal for continued reef growth.

Key words: Foraminifera, SEDCON, FORAM, reefs, sediments.

Introduction

The Florida Fish and Wildlife Research Institute's Coral Reef Evaluation and Monitoring Program (CREMP) has monitored the decline of coral in Florida for over ten years. Their study has shown that coral cover remains highest on patch reefs at the northern end of the reef tract (16% coral cover) (Beaver et al. 2005). The reasons for this trend are not well understood, but may be related to the protection from extreme variations in water quality parameters provided by the near constant presence of islands at the north end of the Florida Keys.

Patch reefs were sampled in Biscayne National Park, FL (Fig. 1), to assess environmental patterns and test two environmental indices. Reefs in this area are protected from direct influence of Biscayne Bay by the presence of Elliot Key and Old Rhode's Key. However, Caesar's Creek, between the two Keys, has a known net outflow of water from the Bay directly onto the reefs.

Two indices have been developed based on Foraminifera and sediment constituents. The FORAM Index and the SEDCON Index were developed to relate the response of the calcifying benthic community to the status and suitability of the environment for future reef growth (Hallock et al. 2003, Daniels 2005). In both indices, shifts in assemblage contribution from mixotrophic organisms (symbiont-bearing foraminifers and coral) to heterotrophic organisms (smaller foraminifers and molluscan fragments) are hypothesized to reflect environmental changes associated with reduced potential for coral reefs to dominate and recover from stress events. The low-cost, easily applied nature of these indices provides a potential new tool for resource managers, especially in regions where technically trained personnel are more affordable than chemical analyses.

Figure 1. Sampling location within Biscayne National Park, FL

Material and Methods

Sediment samples and environmental data were collected from 32 reefs in Biscayne National Park, including 30 patch reefs and two bank-barrier reefs (Pacific Reef and Lugano Reef).

Sediments were wet sieved and the sand fraction was dried. A one gram subsample was removed for the FORAM index analysis. Grain-size analysis was performed on the remaining sample fraction. The 0.5-1mm and 1-2mm size fractions were recombined and a one gram subsample was taken for analysis for the SEDCON index.

For the FORAM Index, up to 150 foraminifers were picked from the 1g subsample. Each specimen was then identified to genus. For the SEDCON Index, 300 grains were randomly chosen from the subsample using a point-count method. Each grain was then identified to the extent possible.

The gathered assemblage data were then used to calculate FORAM and SEDCON Index values according to Tables 1a and 1b. An FI value >4 indicates water quality suitable for dominance by calcifying organisms with algal symbionts. A value from 2-4 indicates conditions where calcifying symbioses can persist but not dominate and may not be able to recover from a stress event. At <2, water quality is probably not suitable for reef growth (Hallock et al. 2003). SI values reflect sediment contributions: SI values >4 reflect sediment production dominated by calcifying symbioses (i.e., coral and foraminifers). From 2-4, dominance is by autotrophic and heterotrophic processes (calcareous algae and non-symbiotic animals); SI <2 reflects dominance by unidentifiable grains presumably reflecting bioerosion.

The SIMPROF and SIMPER tests in PRIMER statistical software (Clarke and Warwick 2001) were used to identify similarities between samples based on assemblage composition for both the foraminiferal assemblages and the sediment constituent assemblages. Surfer surface mapping system and ArcMap were then used to plot the similarity data as well as to create contour lines for temperature, salinity, percent mud, FORAM Index and SEDCON Index values.

Results

Spatial patterns were determined by calculating Moran's I value of spatial autocorrelation (Anselin et al. 2006). A significant value indicates non-randomness. All three environmental variables had significant spatial autocorrelation ($p<0.05$) (Mud - 0.42, Temperature - 0.31 and Salinity - 0.27 respectively). Temperature and salinity negatively correlated with each other (bivariate Moran's I: -0.33). Percent mud also had significant correlations with temperature and salinity (Pearson's ρ = -0.42, 0.53 respectively). The three environmental parameters also spatially correlated with the FI and SI values with significant Pearson's correlations ($p<0.05$) (Figs. 2, 3, and 4).

Table 1. Calculations for a) the FORAM Index and b) the SEDCON Index.

a)

$FI = (10*P_s)+(P_o)+(2*P_h)$	
Where,	$P_s = N_s/T$ $P_o = N_o/T$ $P_h = N_h/T$
And,	T = total number of specimens counted
	N_s= number of symbiont-bearing Foraminifera
	N_o=number of stress-tolerant Foraminifera
	N_h= number of other small, heterotrophic Foraminifera

b)

$SI = (10*P_c)+(8*P_f)+(2*P_{ah})+(0.1*P_u)$	
Where,	$P_c = N_c/T$ $P_f = N_f/T$ $P_{ah} = N_{ah}/T$ $P_u = N_u/T$
And,	T = total number of grains counted (300)
	N_c= number of coral grains
	N_f=number of symbiont-bearing Foraminifera
	N_{ah}=number of coralline algae, calcareous algae, and heterotrophic skeletal grains
	N_u= number of unidentifiable grains

Foraminiferal Analysis

Statistical tests in PRIMER showed sites clustered into five major groups (A, B, C, D, E) based on the foraminiferal assemblage (Fig. 5). Table 2 shows the averages for the environmental data within each cluster as well as the percent contribution by certain foraminiferal groups.

FORAM Index values were calculated in accordance to the formula presented in Table 1a for only those sites where more than 50 specimens were present in a one gram sample. The highest FI values (Fig. 5), correspond to SIMPER groups A and E, with Pacific Reef having the highest average FI value (7.0, SD=1.9). Lowest FI values correspond to SIMPER group C. The lowest FI value was at Bug Reef with an FI of 2.1 (SD=0.12).

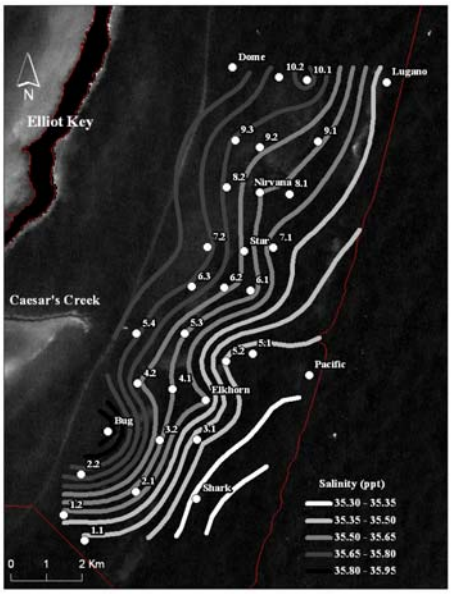

Figure 2. Contour lines of salinity values in the sampling area in Biscayne National Park. The less than 1ppt change over the sampling area indicates that this is not a major factor in shaping the indices patterns.

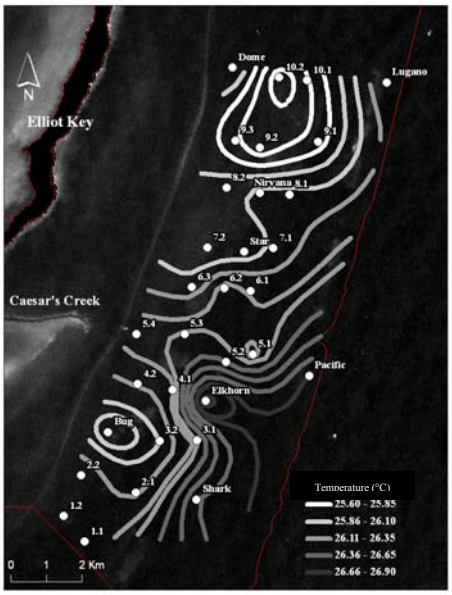

Figure 3. Contour lines of temperature values throughout the sampling area in Biscayne National Park. The less than 2°C change over the sampling area indicates that this is not a major factor in shaping the indices patterns.

Sediment Constituent Analysis

Only two clusters were identified in the sediment constituent data. Both groups were dominated by calcareous algae, mollusks, and unidentifiable grains. Unidentifiable grains dominated Group B which were located in higher energy areas. Table 3 summarizes the environmental data for each sediment constituent defined cluster.

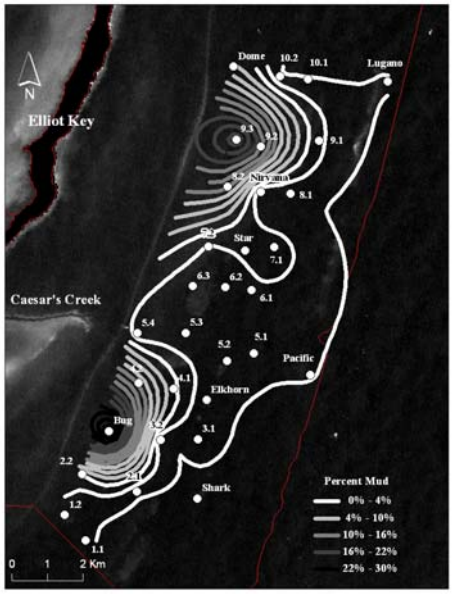

Figure 4. Contour lines of percent mud values throughout the sampling area in Biscayne National Park. The absence of mud offshore of Caesar's Creek and abundance of mud offshore of the Key islands may be influencing, or may indicate another influence that is shaping the patterns seen in the indices.

Unidentifiable grains had a strong negative Pearson's correlation (-0.72) with percent mud, while at the muddiest sites there were more identifiable calcareous algae, which positively correlated to the SI values (0.67)

SEDCON Index values were calculated based on the equation derived in Daniels (2005) and shown in Table 1b. The range of mean values among the reefs was from 0.64 (SD=0.03) at Shark Reef to 2.48 (SD=0.42) at Reef 9.3. The lower SI values are found in the vicinity of Caesar's Creek, while the reefs furthest from direct sources of water flow have higher SI values (Fig. 6).

Discussion

Waters emerging from Biscayne Bay through Caesar's Creek into the study area clearly influence temperature, salinity, sediment texture, and the foraminiferal and sediment -constituent assemblages as reflected in the FORAM and SEDCON Indices.

The SEDCON Index was faster and easier to apply, while the FORAM Index produced more inter-reef detail. However, there was an unanticipated negative Pearson's correlation between the FORAM Index and the SEDCON Index (-0.53). Spatially, the patterns between the two indices co-varied significantly with a Moran's I value of -0.399 (p=0.01).

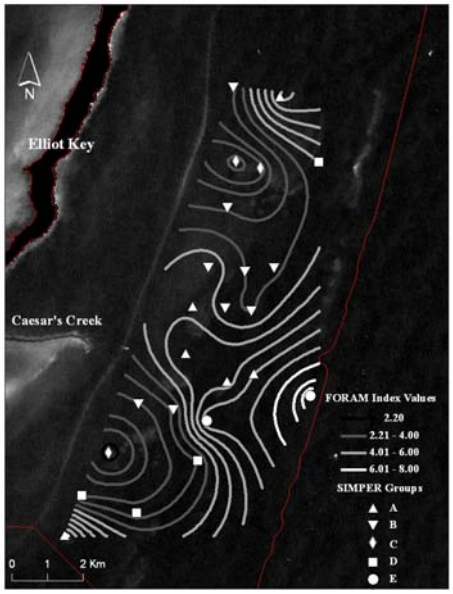

Figure 5. Reefs that clustered together based on similarity of foraminiferal assemblage are indicated with the same symbol. Five cluster groups were identified. Contour lines represent FORAM Index values throughout the sampled area of Biscayne National Park.

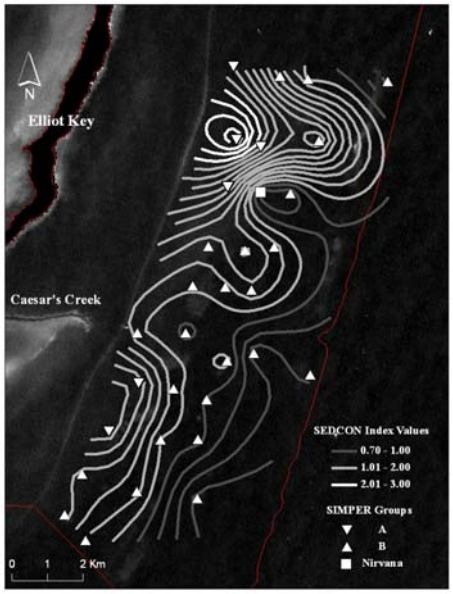

Figure 6. Reefs that clustered together based on similarity of sediment constituent assemblage are indicated with the same symbol. Two cluster groups were identified. Contour lines represent SEDCON Index values throughout the sampled area of Biscayne National Park.

The negative correlation between the two indices appears to reflect the difference between the potential for carbonate production by symbiont-bearing corals and foraminifers, as indicated by the FORAM Index, versus the reality of the decline of coral cover over the past several decades (e.g., Dupont et al. in press), which is reflected in the SEDCON Index. Water quality in the reef area of Biscayne National Park appears to be suitable for calcifying symbioses; the average FI value across all reefs was 4.12. However, the average SI value of 1.26 indicates that potential is not being realized and that erosional processes, and secondarily autotrophic and heterotrophic production, are dominant sources of carbonate sediments associated with BNP patch reefs.

The divergence between the two indices likely indicates that climatic (e.g., hurricanes), regional (e.g., coral diseases) and global (e.g., photo-oxidative stresses) influences are more important than local water quality in the decline of Biscayne patch reefs. Populations of the shorter-lived foraminifers can rebound from mortality events in a few years (Hallock et al. 2006), while long-lived corals have not been able to rebound from successive impacts and mortality events over the past several decades (e.g., Dupont et al. in press).

This study expands upon the original premise of the SEDCON Index, when used in conjunction with the FORAM Index. They were originally both thought to indicate whether water quality supports calcifying symbioses. But this study indicates that the FORAM Index does so, while the SEDCON Index indicates that factors other than water quality can control sediment composition, reflecting more of the history of processes affecting macrobenthos.

Table 2. Summary table of the environmental data averaged for each of the five clusters based on similarity of foraminiferal assemblages, and the % contribution of certain foraminiferal groups to each cluster.

Group	FI	Density (shells/g)	# of Genera	pH	Temperature	DO	Salinity	% Mud	Phi	% Symbiont-bearing	% Stress-tolerant	% Other taxa
A	4.85	126	21.7	8.31	26.09	6.32	35.57	0.55	1.11	34.76	5.24	51.2
B	3.60	957	31.7	8.32	26.08	6.25	35.66	5.76	1.33	22.71	9.12	59

Table 3. Summary table of the environmental data averaged for the two clusters based on sediment constituent assemblages.

Group	SI	pH	Temperature	DO	Salinity	% Mud	Phi
A	1.89	8.26	25.95	6.29	35.75	17.3	2.00
B	1.13	8.29	26.20	6.38	35.58	1.10	0.88
Nirvana	0.85	8.25	26.09	6.43	35.60	0.06	1.00

Conclusions

1. The patterns of salinity, temperature, and percent mud reflect waters emerging from Biscayne Bay through Caesar's Creek into the study area.
2. The influence of the water emerging from the bay is reflected in the FORAM and SEDCON Indices.
3. The SEDCON Index was faster and easier to apply, while the FORAM Index produced more inter-reef detail.
4. The negative correlation between the two indices may reflect the difference between the potential for carbonate production by symbiont-bearing corals and foraminifers, as indicated by the FORAM Index, versus the reality of the decline of coral cover over the past several decades, which is reflected in the SEDCON Index.
5. Water quality in the reef area of Biscayne National Park appears to be suitable for calcifying symbioses; the average FI value across all reefs was 4.12.
6. The average SI value of 1.26 indicates that erosional processes, and secondarily autotrophic and heterotrophic production, are dominant sources of carbonate sediments associated with BNP patch reefs.
7. The divergence between the two indices may indicate that regional (e.g., coral diseases) and global (e.g., photo-oxidative stresses) influences are more important than local water quality in the decline of Biscayne patch reefs.

Abstract. The main goal of this paper is to determine how size (small vs. large coral heads) and age (juvenile vs. adult) potentially affect geochemical proxies in coral skeleton, widely used in paleoclimate studies. After ensuring that corals are not diagenetically altered, we analyse Sr/Ca, Mg/Ca, $\delta^{18}O$ and $\delta^{13}C$ on 3 cores from two study areas. We compare two different size corals from similar environmental setting in Vanuatu. The smaller coral head, despite presenting a similar seasonal shape pattern that its larger counterpart, presents higher Sr/Ca, potentially interpreted as cooler temperatures. We also study the top and the basement of a ~7m-high massive *Porites* sp. core from New Caledonia that reveal both modern and post-settlement periods. A sharp evolution of the geochemical proxies is seen during the post-settlement period. The differences in between the cores seem unlikely to be caused by environmental factors alone and we argue for biological differences. The implications are important for fossil studies where coral cores are often recovered in small pieces with no age indices (adult or young). Geochemical reconstructions should then be carefully interpreted as ontogenic effects could easily bias the results.

Key words: coral, geochemical proxies, paleoclimate reconstruction

Introduction

Massive coral have received growing attention in paleoclimate studies over the years. Coral carbonate skeletons are useful archives containing multiple proxies that could help reconstructing environmental history. In most coral studies, a calibration phase linking geochemical signals to environmental parameters is achieved on the modern part of a core. Calibration equations are then applied to the whole core (Ourbak 2006) or to a fossil piece (Corrège et al. 2004) to evaluate paleoclimate variability. Calibration studies often invokes thermodynamic laws predicting a temperature-related incorporation of trace elements (Sr/Ca for example) and oxygen isotopes ($\delta^{18}O$) in calcium carbonate (Kinsman and Holland 1969; Weber and Woodhead 1972). Calcification in bioconstructed minerals such as coral aragonite have complex incorporation processes and a "vital" effect is invoked to account for biological effects perturbing the pure thermodynamic relationship (Erez 1978).

Several studies have been conducted on biological effects, but only a few indirectly address the potential impact of coral size or age (different growth stages) on the geochemical signals. However, geochemical composition of several marine carbonate species such as benthic and planktonic foraminifera (Bijma et al. 1998; Hintz et al. 2006), or bivalves (Gillikin et al. 2007) present ontogenic effect. Concerning corals, a potential size-effect on the accuracy of Sr/Ca=f (SST) calibration has been published (Marshall and McCulloch 2002); SST stands for sea surface temperature. A comparison of several coral heads along the Great Barrier Reef produced different calibrations. Marshall and McCulloch (2002) suggested that younger corals are less reliable than larger/older corals because of some physiological difference.

Fossil corals are often recovered out of growth position or as fragments. Thus, it is important to study the potential effect of size/age on skeleton geochemical composition as a potential bias to environmental reconstructions. After ensuring that the cores present pristine aragonite, we interpret geochemical results (Sr/Ca, Mg/Ca, $\delta^{18}O$, $\delta^{13}C$).

First, we address the importance of the size of coral heads. We selected two Vanuatu coral heads of different sizes and compare their Sr/Ca composition. Small coral heads capture temperature signal as well as their larger counterparts but the two series present a systematic difference.

Second, we test the age-effect by determining how reliable are the geochemical signals at the basement of a coral core, corresponding to the post-settlement period. We use a ~7m-high massive colony from New Caledonia. At the bottom of the core, 23-years of distinct banding patterns give crucial information on coral post-settlement period.

Material and Methods

Material

All the cores were recovered by SCUBA, sliced, cleaned in deionized water ultrasonic bath and then air-dried.

Two *Porites lutea* cores from Espiritu Santo, Republic of Vanuatu were sampled. A large (~140 cm long) coral head was cored in 1992 within Malo Channel (15.7ºS, 167.2ºE) and described by Kilbourne et al. (2004a; 2004b). The second colony (22 cm high) was collected by hand in July 1979 offshore of Tasmaloum, 34 km away. Chronology established by band counting on X-rays give ages of 65 years and 11 years, respectively, based on a 2cm/year growth rate for both cores. Even though the two sites are situated in similar oceanic settings, episodic terrestrial inputs during the rainy season (May to September) could be important at Tasmaloum site (F. Taylor, pers communication). These episodes affect salinity signal but are usually hours to daylong and should not affect our monthly sampling resolution.

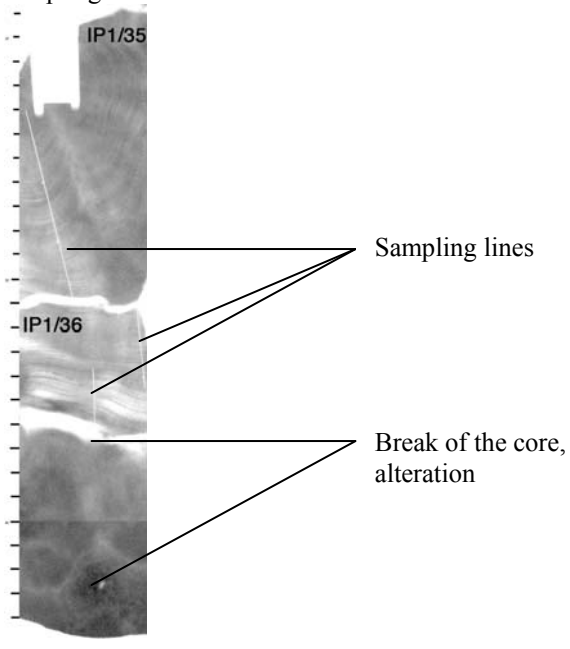

Figure 1: X-Ray of IP1/35 and IP1/36 slices at the very bottom of the New Caledonia coral. Scale on the left: 1 cm in between two ticks. The last 8 cm have been discarded due to absence of clear growth bands and presence of alteration features at the very bottom of the core.

A ~7m-high *Porites sp*. core was collected in 2003 on the outer reef of Ile des Pins, New Caledonia (22.31ºS, 167.25ºE). Results of the more recent 567 cm are discussed in Ourbak (2006). Deeper than 567 cm, about a meter of the core was discarded due to erratic growth patterns. This study focuses on the last two bottom slices (Fig. 1), undated, at the basement of the core, which we expect to correspond to the post-settlement period and the initial growth period of the colony. We chose a constant 0.5 cm per sample (corresponding to a pseudo-half year resolution). A narrow zone of preferential dissolution and complex growth band patterns at the bottom position of the core led us to stop sampling 8 cm before the bottom of the core (slice named IP1/36, Fig. 1).

Methods

Vanuatu Sr/Ca measurements were made using a PerkinElmer Optima 4300 DV ICP-OES (CMS, University of South Florida), following the method for drift corrected from Schrag (1999). An Optima mass spectrometer was used to produce New Caledonia $\delta^{18}O$ and $\delta^{13}C$ data (UMR EPOC, Université Bordeaux 1). New Caledonia Sr/Ca and Mg/Ca ratio were determined with a PerkinElmer Optima 3000 DV ICP-AES (IRD Nouméa). A Siemens D500 diffractometer and a Cambridge Stereoscan 200 scanning electron microscope were used for XRD analysis and SEM images, respectively, at IRD Bondy Ile de France center.

Results and Discussion

Potential diagenetic alteration

Diagenetic features in corals such as secondary deposition of aragonite needles and dissolution processes alter Sr/Ca, Mg/Ca, $\delta^{18}O$ and $\delta^{13}C$ values in fossil cores and even in the very recent part of modern cores (Bar-Matthews et al. 1993; Hendy et al. 2007). This could bias paleothermometers by cooling the temperature as much as 5 ºC (Muller et al. 2001).

XRD (not shown here) does not detect calcite and confirms that New Caledonia coral is made of aragonite. Moreover, SEM image (Fig. 2) presents unaltered primary aragonitic needles with no indications of dissolution. In addition, level of correlation between geochemical tracers increase for altered crystals compared to pristine ones (see Quinn and Taylor (2006), for example). We computed correlation coefficients and did not find any increase of the correlation over the bottom samples (Table 1), ruling out any diagenesis impact on New Caledonia coral. Similarly, The Malo channel Vanuatu core has been previously checked (SEM and petrographic microscope) and do not present diagenetic alteration (Kilbourne et al. 2004a).

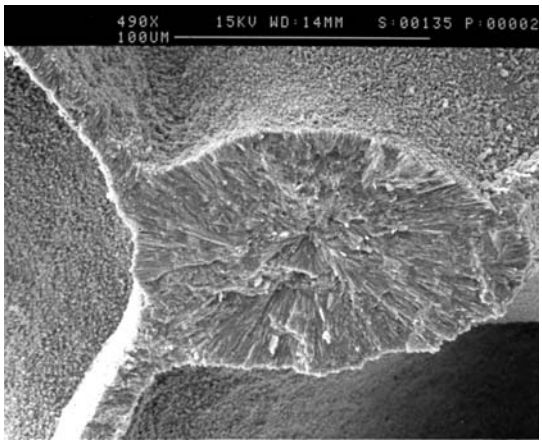

Figure 2: IP1/35 SEM image presents well-preserved dissepiments, broken septa and aragonite needles arguing for a pristine skeletal material, without alteration.

Sr/Ca	*-0.45*	*0.47*	*-0.42*	*-0.60*

Table 1: Correlation coefficients (*r*) between the different geochemical proxies measured in New Caledonia core (*$r > 0.38$, $p < 0.5$, $n = 25$*). δ^{13}Ct stands for $\delta^{13}C_{transformed}$, see text for details. Top (modern) samples are on the right side, in italic while bottom (older) are on the left.

Does size matter? The Vanuatu corals

Marshall and McCulloch (2002) found large differences in Sr/Ca=f (SST) calibration equations from the Great Barrier Reef modern coral heads. They suggest that smaller corals produce less reliable calibrations than larger ones and point that "immature or juvenile coral heads are somehow physiologically different from their more mature counterparts, and this is reflected in their intake of trace elements and isotopes." To our knowledge, no other study dealt with the size of coral heads and its potential influence on geochemical signature over the biomineralized inorganic skeleton.

We tested Marshall and McCulloch's hypothesis on the Vanuatu corals. Kilbourne et al. (2004b) published a modern Vanuatu coral record with 65 years of monthly Sr/Ca data that varied with temperature. We sampled a small coral head (26 cm in diameter, 22 cm high) that was removed from the same island (assuming that Sr/Ca is spatially and temporally constant at the timescales studied). The difference between the mean is 0.096 mmol/mol for 3 years (Fig. 4). Reconstructing the SST based on the Kilbourne et al. (2004b) equation (0.05 mmol/mol of Sr/Ca per 1°C), the SST difference between the cores is 1.9°C, with the smaller head recording cooler temperatures. This is the opposite to what one can expect from the coral locations, as the small coral head lived in a more confine environment than the large coral head (bay vs. open water pass). This study tends to agree with Marshall and McCulloch's (2002) hypothesis regarding size effect on coral Sr/Ca composition.

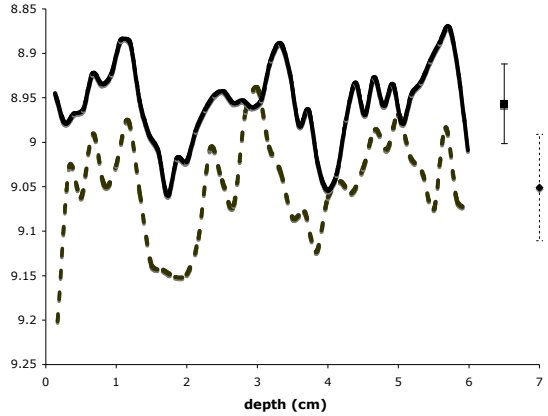

Figure 4: Comparison between Sr/Ca series from a small (dotted line) and a larger Vanuatu coral heads. Mean values are shown with one standard deviation. Sr/Ca scale is inverted to mimic SST.

Does age matter? The New Caledonia coral

Fig. 3 presents geochemical composition (Mg/Ca, Sr/Ca, δ^{13}C and δ^{18}O) of 25 samples from New Caledonia coral. The modern part (top slice) is compared to the basement (bottom slices).

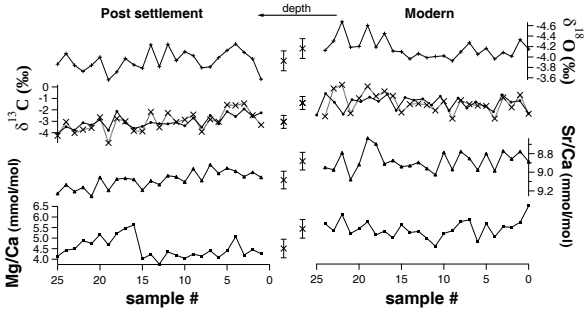

Figure 3: Geochemical data. From bottom to top: Mg/Ca, Sr/Ca, δ^{13}C and $\delta^{13}C_{transformed}$ to remove kinetic effect (crosses, see text for details) and δ^{18}O. The post-settlement period (bottom slices) is on the left and the modern period (top slice) is on the right side. Average values for each series are also shown with one standard deviation, in the center of the figure. 25 samples with half yearly resolution, i.e. ~12.5 years in total, are presented. Sr/Ca and δ^{18}O scales are inverted to mimic sea surface temperature variations.

Concerning the modern period, correlation coefficients between proxies (Table 1) are consistent with previous studies from New Caledonia (Stephans et al. 2004; Ourbak et al. 2006). Sr/Ca and δ^{18}O, anti-correlated to SST, are commonly used as

paleothermometers in corals. Mg/Ca varies with temperature (e.g. Mitsuguchi et al. 1996) which explains the negative correlation with Sr/Ca and $\delta^{18}O$ in Table 1.

The post-settlement period has a different geochemistry than the modern section (Fig. 3 and Table 1). For example, the post-settlement period records the Sr/Ca maximum and the $\delta^{13}C$ minimum of the New Caledonia data presented in Fig. 3 but also of the whole core (over 1000 samples), implying that this period was very different from the rest of the coral history. During the post-settlement period, Mg/Ca show no correlation with Sr/Ca and $\delta^{18}O$. Mg/Ca are on average lower during the post-settlement period vs. modern period (4.50 vs. 5.44 mmol/mol). On the contrary, Sr/Ca and $\delta^{18}O$ show higher averages during the post-settlement period (9.08 vs. 8.88 mmol/mol and -3.92 vs. -4.16‰, respectively). All these proxies vary principally with sea surface temperature and reveal cooler values for the bottom of the core. The average Mg/Ca difference between top and bottom, 0.94 mmol/mol, corresponds to a 4.3°C difference (using 0.218 mmol/mol per °C, Ourbak et al. (2006)). A 3.8°C SST variation is recorded in Sr/Ca (using a -0.0528 mmol/mol per °C (Ourbak 2006)) and $\delta^{18}O$ records a 1.5°C difference but this value could be subdued by the salinity influence on $\delta^{18}O$.

Although undated, based on extension rate and the total length of the core, we project the post settlement period ~7 centuries ago. A ~4°C is cooler than any similar record for the last millennium and would equate to the Younger Dryas 4.5°C cooling recorded in a Vanuatu coral (Corrège et al. 2004) (to compare with 1.4°C cooling during the Little Ice Age (1701-1761) period in New Caledonia (Corrège et al. 2001)). This would imply that temperature doesn't have the same effect on Sr, Mg and oxygen isotopes incorporation at the early stage of life of this coral compare to nowadays or that other parameters affect Sr/Ca, Mg/Ca and $\delta^{18}O$.

$\delta^{13}C$ is on average lower during the post-settlement period than the modern period (-3.05 vs. -1.4‰). One plausible factors causing $\delta^{13}C$ difference between New Caledonia slices could be the light-effect and its potential metabolic shift associated. According to several studies (see Ourbak et al submitted, and references therein) the ~7m difference between top and bottom slices could be sufficient to affect $\delta^{13}C$ signal by a 1.4‰ range as shown here (see depth-effects in the $\delta^{13}C$ composition e.g. McConnaughey 1989). This hypothesis alone is appealing but one should keep in mind that $\delta^{13}C$ in coral skeleton is difficult to interpret due to multiple affecting factors (Dissolved Inorganic Carbon, Photosynthesis/ Respiration rate, kinetic and metabolic factors etc). We also present $\delta^{13}C_{transformed}$. A mixture of kinetic isotope effects (resulting in isotopic depletion of carbon relative to isotopic equilibrium) and an equilibrium process control isotopic composition of corals. We applied a simple data transformation to correct for disequilibrium kinetic influences and to emphasize $\delta^{13}C$ metabolic signals only ($\delta^{13}C_{transformed} = \delta^{13}C_{original} - 3*(\delta^{18}O_{original} - \delta^{18}O_{average})$), see Heikoop et al. 2000). $\delta^{13}C_{transformed}$ show that kinetic effects at the early stage of life had the same range of effect on $\delta^{13}C$ signal than later in life (Fig. 3).

An explanation of the results presented here could be that ontogenic effects affect coral geochemical composition. Only a few studies have reported geochemical signature of the time of post-settlement of corals. In a very high resolution study (50 samples per year), Gagan et al. (1996) report on spawning events of two coral heads from two different reefs. A reproductively mature colony from Pandora Reef (6 years of growth at the top of a ~300 years old massive *Porites*) "revealed sharp ^{13}C enrichments closely corresponding to the time of the annual synchronized coral spawning event" and $\delta^{13}C$ and $\delta^{18}O$ signals are in phase. On the contrary, a small colony ~15 years old from Ningaloo Reef present no $\delta^{13}C$ annual variations for the first 6 years and when variations happen, $\delta^{13}C$ is out of phase with $\delta^{18}O$ signal. Gagan et al. (1996) suggest, "$\delta^{13}C$ signature is linked to the chemistry of the early reproductive patterns typical of juvenile massive corals". Thus monotonous $\delta^{13}C$ signature would correspond to years without reproduction, and subsequent shift to greater $\delta^{13}C$ variability would reflect the onset of "adolescence" of the coral, punctuated by brief annual reproductive cycles.

Even if our study misses the very first years of the post-settlement and our sampling resolution does not capture reproductive cycles, the ~2‰ $\delta^{13}C$ increase over the first 25 samples is similar to the one observed by Gagan et al (see Gagan et al 1996, Fig. 1B) concerning the differences between non-reproductive and reproductive years. Based on our preliminary results, we can anticipate that slice IP1/36 does not reflect environmental variability but rather is geochemically affected by early stage of growth and that Sr/Ca, Mg/Ca and $\delta^{18}O$, commonly used as SST proxy reveal erroneous reconstructed temperature.

Preliminary conclusions and implications for coral research.

We compared coral skeleton geochemical composition recorded by two different size Vanuatu corals and by the top and the basement of a New Caledonia core and find in both case large variations.

Mean Sr/Ca show a systematic shift in between small and larger Vanuatu corals. The Sr/Ca, Mg/Ca, $\delta^{18}O$ and $\delta^{13}C$ reveal anomalous values between New Caledonia core sections that are not due to diagenetic perturbations. We propose they are the results of ontogenic effects.

If one apply a calibration equation initiated from a large coral head to a small coral head, as it is often the case in fossils studies, the absolute temperature reconstruction could be biased by as much as 1.9°C based on Vanuatu example. Moreover, in a best-case scenario, when calibration is from the same core, ontogenic effects could alter the geochemistry at the youngest portions, thus introduce a bias in SST reconstruction, as demonstrated in the New Caledonia core.

These findings have important implications for paleoenvironmental studies, as in small coral colonies, as well as juvenile parts, one should be aware of the potential size/age effect and interpret Sr/Ca results in terms of relative changes rather than absolute temperature value. In other words, temperatures reconstructed from a fossil coral not collected in growth position, i.e. without indices of total length or age of the specimen could be biased if the coral has not reached maturity. Could we find a size threshold corresponding to sexual maturity for commonly used coral species? Can we quantify the ontogenic effect to discriminate against climatic factors affecting coral proxies? Numerous questions remain and further studies are needed to better understand biomineralization processes and how ontogenic factors affect the geochemical composition of coral skeleton.

Abstract. For better understanding of carbon isotope systematic of coral skeleton, two different coral species growing next to each other, *Porites sp.* and *Platygyra ryukyuensis*, were collected at a site from Ishigaki Island, Japan, and analyzed for oxygen and carbon isotope ratios. Oxygen isotope ratios of both corals show seasonal variations well matching each other and that of observed sea surface temperatures. However, carbon isotope ratios were opposed in trends between two coral species. Carbon isotope ratios of *Porites* show a seasonal fluctuation matching that of solar radiation, while those of *Platygyra* are opposite in trend to that of solar radiation with weaker amplitude. Given that both coral colonies had been exposed to same environmental conditions during the growth period, these opposite trends should be attributed to different species-dependent vital response to the same environmental condition. A vector analysis indicates that seasonal variation of carbon isotope ratios are dominantly controlled by metabolic isotopic effect in both corals and also that the opposite trends in seasonal fluctuations of two coral species result from the opposite direction of metabolic isotope effect acting on two coral species. *Porites* shows a negative slope in a $\delta^{18}O$-$\delta^{13}C$ plot, in which seasonal shifts of $\delta^{18}O$ and $\delta^{13}C$ from colder to warmer season are explained with increased temperature and increased photosynthesis/respiration (P/R) ratios, indicating increased food-dependency on symbiotic algae (autotrophy) during warmer season. In contrast, *Platygyra* shows a positive slope in a $\delta^{18}O$-$\delta^{13}C$ plot, in which seasonal shift of $\delta^{13}C$ to summer is caused by decreased P/R ratios, indicative of reduced dependency on autotrophy during warmer season. This physiological characteristic of *Platygyra* might provide a tolerance to colder and weaker solar radiation environmental condition, which allows its wide distribution in middle latitude region.

Key words: coral skeleton, carbon isotope compositions, species dependency, *Porites*, *Favia*.

Introduction

Geochemical composition of reef-building coral skeleton has been a popular tool for high-resolution paleoclimatic reconstructions because coral skeleton shows systematic seasonal changes in isotopic and elemental compositions according to seasonal environmental changes. In particular, the stable oxygen isotopic values ($\delta^{18}Oc$) and Sr/Ca ratios of coral skeleton have proven to be reliable proxies for sea surface temperature (SST) and salinity (SSS) (Gagan et al. 2000). Boron isotopic composition, Cd/Ca, U/Ca ratios have been used as pH, upwelling, and temperature indicators, respectively (Pelejero et al. 2005; Reuer et al. 2003; Min et al. 1995).

Various controlling factors have been proposed for carbon isotopic value of coral skeleton ($\delta^{13}Cc$), including the $\delta^{13}C$ of dissolved inorganic carbon (DIC) in seawater (Nozaki et al. 1978; Swart et al. 1996), light intensity for photosynthesis of the zooxanthellate (Weber and Woodhead 1970; Swart 1983; Wellington and Dunbar 1995; Reynaud-Vaganay et al. 2001; Grottoli 2002; Asami et al. 2004; Shimamura et al. 2008), utilization and $\delta^{13}C$ of CO_2 originating from respiration (Swart et al. 2005), kinetic isotope effects (KIE) related to the coral calcification rate (McConnaughey 1989a,b; Omata et al. 2005; Suzuki et al. 2005), changes in the coral autotrophy/ heterotrophy diet (Carriquiry et al. 1994; Felis et al. 1998; Grottoli 2002), and coral spawning (Gagan et al. 1994, 1996). However, vital effects and physical controlling mechanisms of $\delta^{13}Cc$ are not fully understood yet. Because of it, the carbon isotopic value of coral skeleton ($\delta^{13}Cc$) has limited applicability in paleo-environmental reconstructions, other than chronology of long-lived coral records (e.g., Cole et al. 1993). Given that $\delta^{13}Cc$ is measured simultaneously with $\delta^{18}Oc$, shows seasonal variation as clearly as $\delta^{18}Oc$ does, and reflects both environmental and biological signals, it has great

potential as a powerful tool for paleo-environmental reconstructions.

For better understanding of controlling factor of δ^{13}Cc, two different coral species growing next to each other, *Porites sp.* and *Platygyra ryukyuensis*, were collected at a site from Ishigaki Island, Japan, and analyzed for δ^{13}Cc and δ^{18}Oc. The results were compared with observed environmental variables. *Platygyra* is one of hermatypic reef building massive corals that show a wide geographical distribution from tropics to higher latitude regions up to 35°N in the northwest Pacific (Yamano et al. 2004). Its geographical distribution extending to middle latitude region could allow us the development of a coral environmental proxy that can be used for middle latitude region. *Porites* was sampled together for the comparison with the results of *Platygyra* because it has provided reliable reconstructions of environments in tropical to subtropical regions of low latitude.

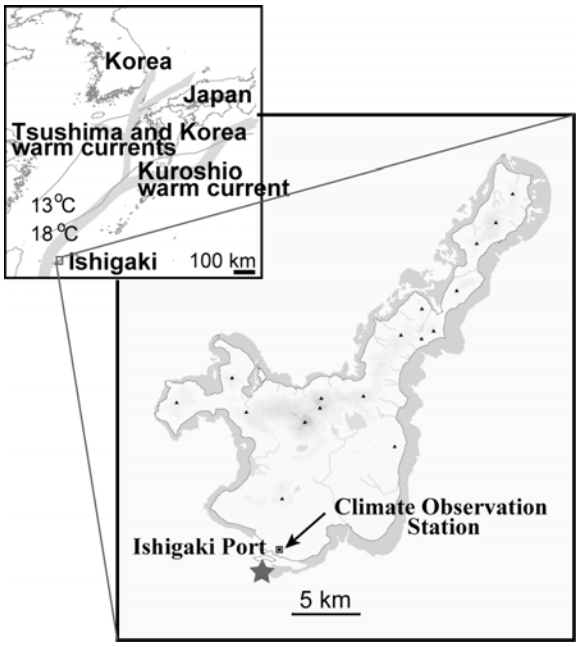

Figure 1: Location map showing the coral sampling sites (star mark) and climate observation station operated by Meteorological Agency of Japan.

Study site and method

Ishigaki Island is located in the southern part of Ryukyu Island Chain, Japan (Fig. 1). Two coral colonies, *Platygyra ryukyuensis* and *Porites spp*., each ~20cm in height, were collected in September, 2005 at 2 m water depth below mean sea level near the Ishigaki Port in the southern part of Ishigaki Island (Fig. 1). The coral collection site (24°25'N, 124°09'E) is about 30 m away from the seawall of the port, facing open ocean. The coral colonies had grown next to each other and thus had been exposed to the same environmental conditions (i.e. SST, SSS, light intensity, δ^{13}C of DIC, and etc.). SST and light intensity were observed at a climate observation station of Japan Meteorological Agency, located in the Ishigaki Port (Fig. 1). The highest light intensity were observed in June–July, whereas the highest SST is recorded in July–August during the study period

The collected coral samples were cut into 5 mm-thick slabs oriented parallel to the maximum growth axis. These slabs were cleaned with de-ionized water and X-rayed using an M-60 (SOFTEX Co). The X-radiographs of the coral slabs showed clear image of corallites, the skeleton of an individual polyp, and annual growth bands (Fig. 2). A continuous corallite along the major growth axis was selected from each slab for micro-sampling (Fig. 2).

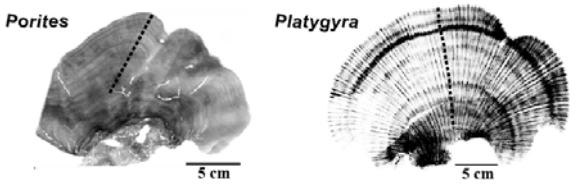

Figure 2: Positive prints of soft X-ray radiographs of coral slabs with micro- sampling transects (dashed lines).

Micro-sampling was carried out using a ledge micro-sampling technique (Gagan et al. 1994). For each sample, a 1-mm-thick and 3-mm-wide ledge was prepared along the selected corallite. The ledges were then ultrasonically cleaned with distilled water and dried in an oven at 40°C. Micro-sampling was undertaken on an accurate-distance (±10μm) movable table at a 200μm interval using a 0.8-mm-diameter end-mill drill bit mounted on a micro-milling machine. Such a sampling interval provides the time resolution of ~ 6 days for *Platygyra* and ~10 days for *Porites*, but the δ^{18}O and δ^{13}C measurement were undertaken at a time resolution of 25 and 20 days at peak areas, respectively. For *Porites*, sampling was carried out for one corallite that includes theca wall, columellae, and septa because of narrow width of corallite (av. 1mm). *Platygyra* was sampled only along the theca wall because of a wide corallite width (3 ~ 4.4mm) and absence of robust columellae and septa structures.

Powdered coral samples were reacted with 100% phosphoric acid at 70.0˚C in an automated individual-carbonate reaction device (Kiel Device) coupled with a Finnigan MAT 251 mass spectrometer. The resulting CO_2 gas was calibrated using NBS-19 standard. The oxygen isotopic ratio for the sample was reported relative to the Vienna Pee Dee Belemnite (V-PDB) in conventional delta notation. The precision for the analysis were 0.07‰ for both

$\delta^{18}O$ and $\delta^{13}C$ based on replicate measurement of NBS-19 standard (n=25).

Results

Both corals show a clear seasonal variation in $\delta^{18}Oc$ that agree with that of SST (Fig. 3). However, $\delta^{13}Cc$ shows different fluctuation pattern between *Platygyra* and *Porites* in magnitude and seasonality. $\delta^{13}Cc$ of *Porites* varies from 0 to -5‰ for the time period of 1995 to 2005 with a clear seasonality, higher values in summer and lower values in winter. This seasonal fluctuation pattern is in phase with that of solar radiation (Fig. 3). In contrast, *Platygyra* shows $\delta^{13}Cc$ values varying from 0 to -4‰ values with weaker seasonality that is opposed to that of *Porites*, higher in winter and lower in summer (Fig. 3). Since both corals had been exposed to the same environmental conditions during their growth period, these opposed trends should be attributed to the species-dependent vital factors, such as kinetic isotope effect due to different calcification rates between two species or different species-dependent physiological responses of two species to the same environmental condition. Seasonal extension rate and calcification rate, estimated based on $\delta^{18}Oc$ variation and x-ray photo analysis, do not show correlation with $\delta^{13}Cc$, which means these variations cannot be explained by KIE.

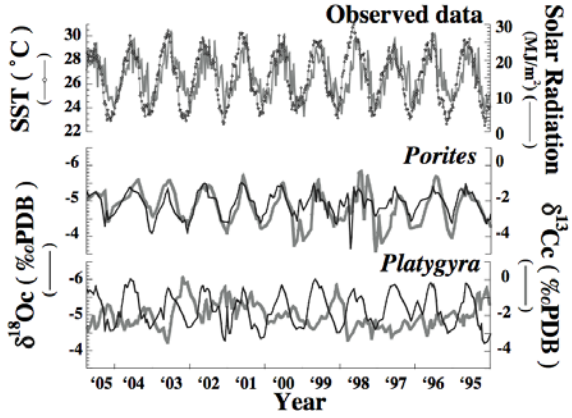

Figure 3: Temporal variation of the observed sea surface temperature and solar radiation, and the measured oxygen and carbon isotope ratios of *Porites* and *Platygyra* during the growth period

Discussion

In order to understand controlling factors responsible for the opposed seasonal variation in the carbon isotope ratios of two coral species, we carried out a vector analysis similar as in McConnaughey (1989) and Omata *et al.* (2005). In this approach, variation of $\delta^{13}Cc$ and $\delta^{18}Oc$ is explained with sum of three vectors with magnitude and direction: 1) temperature dependency of $\delta^{18}Oc$; 2) metabolic isotope effects (MIE) controlled by photosynthesis of symbiotic algae and respiration; and 3) KIE related to calcification rate of skeleton (Fig. 4).

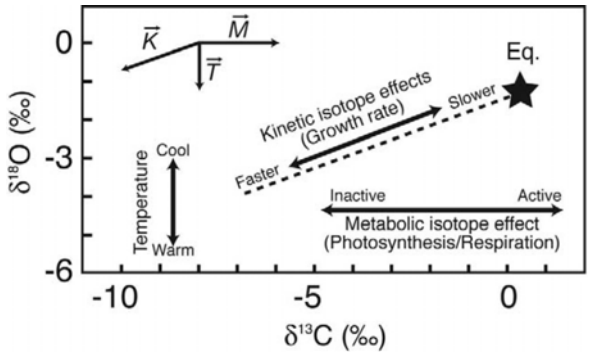

Figure 4: Schematic diagram showing the effects of temperature, kinetic isotope effect and metabolic isotope effect on $\delta^{13}C$ and $\delta^{18}O$, adapted from Omata *et al*. (2005). Eq.: isotopic composition of biogenic carbonate precipitated under isotopic equilibrium; K, M, and T: vectors representing the magnitude and direction of kinetic isotope effect, metabolic isotope effect, and temperature, respectively.

We plotted the determined $\delta^{18}Oc$ and $\delta^{13}Cc$ values in a $\delta^{18}Oc$-$\delta^{13}Cc$ plane on a yearly base (Fig. 5 as an example). In these plots, *Porites* always shows negative slope for all the years from 1995 to 2005 (Fig. 5), in which seasonal shift of $\delta^{18}Oc$ and $\delta^{13}Cc$ from winter to summer can be explained by the sum of negative vector of temperature and positive vector of MIE with a little change in KIE. Negative vector of temperature indicates increase in temperature and positive vector of MIE represents increase in the ratio of photosynthesis to respiration (P/R) toward warmer season. Active photosynthesis of symbiotic algae during warmer season is responsible for the positive vector of MIE.

For the result of *Platygyra,* the slope against whole values showed positive slope in a $\delta^{18}Oc$-$\delta^{13}Cc$ plot for all the analyzed year (Fig. 5). For each vector components, little variation in magnitude of KIE between seasons as in *Porites,* MIE causes negative $\delta^{13}Cc$ shifts because of the negative vector, and it is opposite to that in *Porites*. It means high P/R ratios during winter and non-active photosynthesis by symbiotic algae during warm season or much higher dependency of zooplankton. Also in general, MIE variation is much greater than KIE.

In contrast, *Platygyra,* shows positive slope in a $\delta^{18}Oc$-$\delta^{13}Cc$ plot (Fig. 5), in which seasonal shift of $\delta^{18}Oc$ and $\delta^{13}Cc$ from winter to summer is now explained by the sum of negative vector of temperature, same as in *Porites*, and negative vector of MIE, opposite to that of *Porites* (Fig. 5). As in *Porites*, KIE has negligible effect on seasonal variation of $\delta^{18}Oc$ and $\delta^{13}Cc$ (Fig. 5). Negative vector

of MIE indicates increased importance of respiration relative to photosynthesis during warmer season in *Platygyra*. It can not be conclusive, but might suggest that *Platygyra* is less dependent on autotrophy (food source from symbiotic algae) during warmer season. This physiological characteristic of *Platygyra* might provide a tolerance to colder and weaker solar radiation, which allows wide distribution of *Platygyra* in middle latitude region.

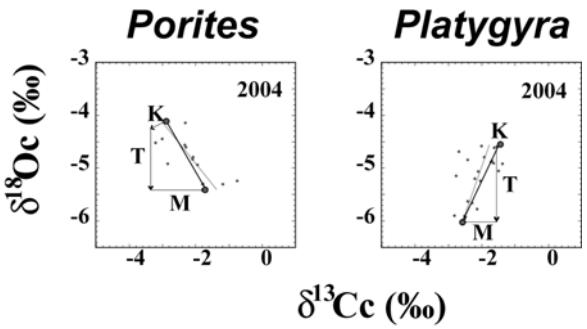

Figure 5: Vector approaches to explain seasonal changes of carbon and oxygen isotopic ratios of the studied corals. K, M, and *T* show the direction and magnitude of the kinetic, metabolic, and temperature effects, respectively.

Conclusions

Oxygen isotopic ratios of *Porites sp.* and *Platygyra ryukyuensis* that had grown next to each other show seasonal variations well matching each other and that of observed sea surface temperatures. However, carbon isotope ratios were opposed in trend between *Porites* and *Platygyra*. Carbon isotope ratios of *Porites* showed a seasonal fluctuation matching that of solar radiation, while those of *Platygyra* were opposite in trend to those of solar radiation and *Porites*. Given that both coral colonies had been exposed same environmental conditions, these opposed trends are likely attributed to species-dependent vital factors rather than environments.

Vector analysis indicates that seasonal variation of δ^{13}Cc is dominantly controlled by MIE over KIE in both corals. *Porites* shows a negative slope in a δ^{18}O-δ^{13}C plot, in which seasonal shifts of δ^{18}O and δ^{13}C from colder to warmer season are explained by increased temperature and photosynthesis/respiration (P/R) ratios, indicating more dependency on food from symbiotic algae during warmer season. In contrast, *Platygyra* shows a negative slope in a δ^{18}O-δ^{13}C plot and decreased P/R ratios during warmer season, indicative of reduced dependency on autotrophy during warmer season.

Abstract. Uranium incorporation into coral skeleton of *Goniastrea aspera* was investigated in the laboratory incubation for 8 hours under controlled pCO_2 and temperature. Seawater parameters such as pH and alkalinity as well as calcium and uranium concentrations were measured every 2 hours. pH increased progressively from 8.17 at initial to 8.54 at the end. In contrast, alkalinity significantly decreased from 2292 to 1467 mmol/kg. The apparent distribution coefficients of uranium, λUO_2, between *Goniastrea aspera* skeleton and seawater were obtained to be 2.7 to 0.7. The data were compiled with those of other studies and the overall data illustrate a negative correlation between λUO_2 and $a CO_3^{2-}$ with the slope of −0.75. It is suggested that variation of carbonate ion activity (i.e. carbonate system) controls the distribution coefficient of uranium and hence coral U/Ca. The effect of uranyl carbonate complexes formation on uranium incorporation is discussed.

Key words: Uranium, distribution coefficient, proxy, carbonate system

Introduction

Carbon dioxide is an extremely important greenhouse gas in the atmosphere, playing a significant role in controlling the Earth's surface temperature. The atmospheric carbon dioxide level has already increased from the concentration of 280 ppm in the pre-industrial age to ~380 ppm today, and it is predicted to reach ~560 ppm before the end of the 21st century (Prentice et al. 2000). Due to the capability of the ocean as a significant reservoir of carbon dioxide from atmosphere, such increases of atmospheric carbon dioxide have some impacts to either physical or chemical properties of oceanic seawater. One of the impacts is the decline of CO_3^{2-} concentration in seawater which is in advance modifying the carbonate system of the surface ocean and eventually affects the metabolism, such as photosynthesis and calcification of marine organisms.

During calcification process of coral, some metal ions are able to be incorporated into carbonate lattice through the ion exchange mechanism between metal and calcium ions. Distribution coefficient of metal (D_{Me}) between coral skeleton and seawater is defined as follows (McIntire 1963; Shen and Boyle 1986; Lea and Spero, 1992):

$$D_{Me} = \frac{[Me/Ca]_{coral}}{[Me/Ca]_{seawater}} \quad (1)$$

For the case of uranium, Shen and Dunbar (1995) reported that the range in the coral/seawater uranium distribution coefficient is 0.8−1.0 once uranium concentration is 13.4 nM (Chen et al. 1986). Furthermore, several studies have been measured the uranium distribution coefficient of 0.5−2.0 which is depended on the coral species (Veeh and Turekian 1968; Schroeder et al. 1970; Thompson and Livingston 1970; Flor and Moore 1977; Swart and Hubbard 1982). The measurement of the distribution coefficient of uranium between carbonate and solution is a useful tool for the understanding of the factors controlling the uranium contents of marine calcareous sediments (Kitano and Oomori 1971; Min et al. 1995).

It is well known that uranium in seawater exists not only a uranyl ion (UO_2^{2+}) (Ku et al. 1977) but also anion complexes with carbonate (i.e. $UO_2CO_3^0$, $UO_2(CO_3)_2^{2-}$ and $UO_2(CO_3)_3^{4-}$) (Grenthe et al. 1992; Shen and Dunbar 1995). It is believed that the formation of such uranyl carbonate complexes is influenced by the carbonate system of seawater. One of parameters to control carbonate system is the carbonate ion activity. Based on this fact, the incorporation mechanism of uranium into coral skeletons is considered as UO_2^{2+} (cation mode) (Kitano and Oomori 1971; Broecker and Peng 1982) or $UO_2(CO_3)_2^{2-}$ (anion mode) (Swart and Hubbard 1982; Shen and Dunbar 1995). Such mechanism remains unclear and nowadays still in debate. In this study, the incubation experiment of coral *Goniastrea aspera* was done to test that carbonate ion activity of solution affects the uranium incorporation into coral

skeleton. The incorporation mode (i.e. cation versus anion mode) of uranium is discussed.

Material and Methods

Coral incubation

We used a coral colony of *Goniastrea aspera* for incubation experiment. Fig. 1 shows a schematic picture of coral incubation. We incubated *G. aspera* (18×26×15 cm^3) in the seawater tank (27×38×24 cm^3) under direct sunlight for 8 hours, and collected seawater samples in the polyethylene bottles every two hours. Photon flux was measured to be 200−800μmol/m^2/s and temperature of the system was 24.5±1.5°C during incubation.

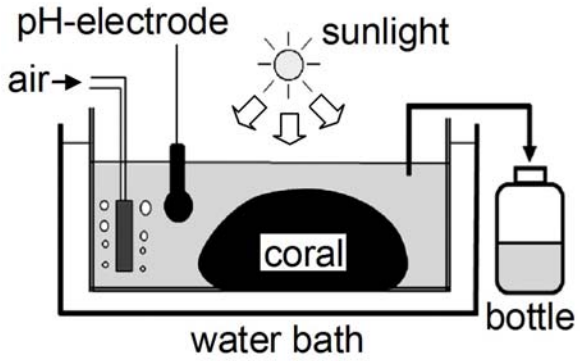

Figure 1: Schematic picture of incubation experiment.

Seawater analysis

The seawater pH was measured immediately after collecting seawater sample. The collected seawater was filtered on a Millipore HA (0.45 μm pore size) filter, and analyzed for alkalinity. The remaining seawater sample was preserved by adding conc. HCl to pH=2, and then was stored for subsequent analysis of total Ca and U.

The pH of seawater was measured by pH meter (Orion 290 A+Thermo, Japan). In each set of measurement, pH meter was calibrated using NBS-scaled buffer solutions (TOA, Golden buffer) at pH=7 (6.863) and pH=4 (4.006) at 25°C. Reproducibility of the measurements (n=11) was found to be ±0.003 pH unit (1σ).

Total alkalinity was measured potentiometrically using an auto titration system (TIM 860 Radiometer, TitraLab, France). Reproducibility of the measurements (n=9) was found to be ±3 μmol/kg (1σ).

Water salinity was measured by a salinometer (Model 8410A, Canada) using the reference standard seawater of IAPSO (K_{15}= 0.99987, S=34.995). Reproducibility of the measurements (n=11) was ±0.001‰ (1σ).

Calcium in seawater samples were determined by EGTA titration method (Kanamori and Ikegami 1980) using an auto titration system (TIM 865 Radiometer, TitraLab, France) equipped with Ca selective electrode. The equivalence point for each titration was obtained by a Gran's plot method. Reproducibility of the measurements (n=11) was ±0.01 mmol/l (1σ).

For the determination of uranium in solution, 15 ml of seawater sample in 30 ml of conc. HCl was passed firstly to anion exchange resin (Dowex 1×8, 100~200 mesh) column to separate uranium from matrix elements. After washed with 8N HCl, sample was eluted by 25 ml of 0.1 N HCl. Recovery of the separation was ~98% and reproducibility of the measurement of 3 ppb uranium was ±0.08 ppb (n=10; 1σ). The eluted-seawater samples were then introduced to ICP-MS (Hewlett Packard, HP 4500) with Ar-H_2 gas carrier for uranium quantification.

The apparent distribution coefficient of uranium (λ_{UO_2}) associated with CO_3^{2-} ion activity during experiment was calculated with the Doerner-Hoskins' equation (Doerner and Hoskins 1925; Kitano et al. 1968):

$$\lambda_{UO_2} = \frac{\log(M_{UO_2,initial} / M_{UO_2,final})}{\log(M_{Ca,initial} / M_{Ca,final})} \quad (2)$$

where $M_{i,initial}$ denotes the molar concentration of i species dissolved in an incubated seawater at t = 0 and $M_{i,final}$ denotes i species at a given time of reaction.

Results

The temperature ranged from 23−26°C during incubation was a suitable circumstance for metabolism of coral (Coles and Jokiel 1977). Parameters such as pH and alkalinity with respect to coral metabolism changed during experiment. Fig. 2 shows the measurements of pH, alkalinity and salinity of seawater every 2 hours of incubation. pH value ranged from 8.17 at initial to 8.54 at the end with average value of 8.43 (Fig. 2a). The calcification process in which the calcium carbonate skeleton was formed diminished carbonate ions from incubated seawater. Such process decreased the alkalinity from 2292 to 1467 μmol/kg (Fig. 2b). However, for the case of salinity, it slightly increased from 34.6 to 35‰ (Fig. 2c), indicating to a slight evaporation during experiment. Shen and Dunbar (1995) suggests that U/Ca ratio in corals is affected by salinity changes in areas subject to significant rainfall or run-off, however, the salinity changes in this study are on a small scale to have impact to the coral U/Ca.

It is considered that the difference in calcium concentration in solution between initial (t=0) and every two hours of incubation time refers to the

amount of cumulative precipitated $CaCO_3$ during the time (Fig. 3). Therefore, due to calcification process, the cumulative amount of $CaCO_3$ increased from 0 at initial to 0.41 mmol/l at the end of experiment. Moreover, during calcification process uranium was incorporated into coral skeleton as indicated by the enhancement of precipitated uranium from 0 to 0.4 nmol/l (Fig. 3b).

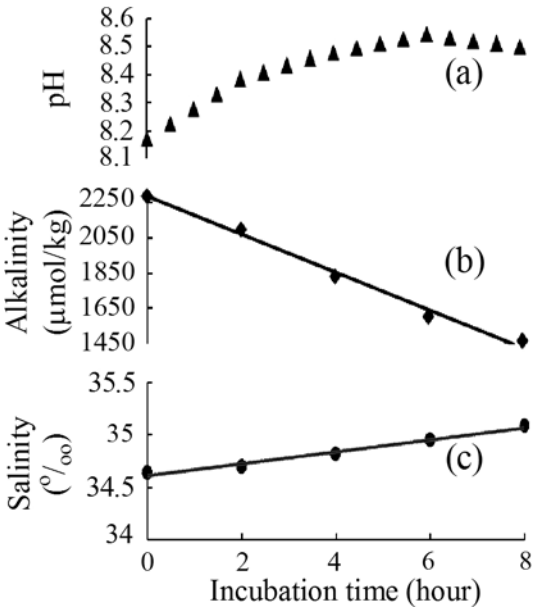

Figure 2: pH, alkalinity and salinity of seawater during experiment.

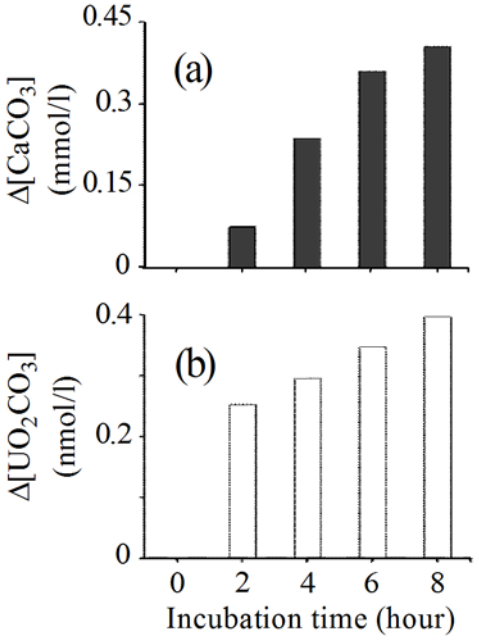

Figure 3: Amount of cumulative precipitation of $CaCO_3$ and UO_2CO_3 every two hours of incubation time.

Fig. 4 shows the relationship between apparent distribution coefficient of uranium and the carbonate ion activity during experiment. In the present study, distribution coefficient decreased from 2.7 to 0.7 as the carbonate ion activity declined from 5 to 4.4 μmol/l. The distribution coefficient data obtained from different coral species as well as inorganic precipitation experiment are also plotted in Fig. 4. The compiled-data reveal a trend of negative correlation between distribution coefficients of uranium and carbonate ion activities with the slope of –0.75.

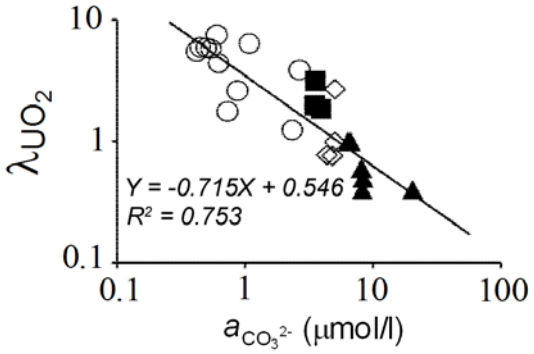

Figure 4: Distribution coefficient of uranium (λUO_2) plotted against the carbonate ion activity (aCO_3^{2-}). ○ = Takaesu, 2008 (Porites sp); ■ = Yoshida, 2000 (Fungia sp); ◇ = this study (*Goniastrea aspera*); ▲ = Kitano and Oomori, 1971 (Inorganic precipitation). The slope of regression line = –0.715.

Discussion

Incorporation of uranium into coral (*Goniastrea aspera*) skeleton under carbonate system change has been a focal point of this study. Fig. 4 shows that the value of the apparent distribution coefficient of uranium (λUO_2) decreased as the carbonate ion activity increased. This phenomenon is considered to be associated with the evidence that uranyl ions form complexes with carbonate ions in solution (Grenthe et al. 1992; Turner et al. 1981). Degree of complex formation of uranyl carbonate increases with increasing carbonate ion activity. Therefore, with increasing of carbonate ion activity, the activity of free uranyl ion dissolved in solution decreases and the distribution coefficient value should decrease (Kitano and Oomori 1971). Speciation of uranyl carbonate complexes in solution is important to discuss the incorporation mechanism of uranium into coral skeleton.

Turner et al. (1981) measured the stability constant (K) for the formation of carbonate species at T=25°C, P=1 atm, I=0.7, as follows:

$UO_2^{2+} + CO_3^{2-} \Leftrightarrow UO_2CO_3^{0}$; $K_1 = 10^{6.02}$

$UO_2^{2+} + 2CO_3^{2-} \Leftrightarrow UO_2(CO_3)_2^{2-}$; $K_2 = 10^{15.07}$

$UO_2^{2+} + 3CO_3^{2-} \Leftrightarrow UO_2(CO_3)_3^{4-}$; $K_3 = 10^{20.19}$

As far as the incorporation of uranium into coral skeleton is concerned, the species being incorporated can be either UO_2^{2+} (cation) or $UO_2(CO_3)_2^{2-}$ (anion) if the incorporation follows the ion exchange process stoichiometrically.

Cation hypothesis

Reaction: $CaCO_3 + UO_2^{2+} \Leftrightarrow UO_2CO_3 + Ca^{2+}$

In this system, a uranyl ion (charge = +2) in solution replaces a similar charge of calcium in solid ($CaCO_3$) phase. The distribution coefficient of uranium (K_{UO_2}) is given as follows:

$$K_{UO_2} = \frac{[UO_2CO_3]}{[CaCO_3]} \cdot \frac{[Ca^{2+}]}{[UO_2^{2+}]} \quad (3)$$

Theoretically, the apparent distribution coefficient of uranium is written (Kitano and Oomori 1971):

$$K_{UO_2} = \frac{1}{1+\alpha} \cdot K^{T}_{UO_2} \cdot \frac{\lambda^{S}_{CaCO_3}}{\lambda^{S}_{UO_2CO_3}} \cdot \frac{\gamma^{L}_{UO_2^{2+}}}{\gamma^{L}_{Ca^{2+}}} , \quad (4)$$

Where γ^L and λ^S denote the activity coefficients of ion species in solution and $MeCO_3$ in carbonate phase respectively, $K^{T}_{UO_2}$ is thermodynamic distribution coefficient of uranium. When $\lambda^{S}_{CaCO_3}$, $\lambda^{S}_{UO_2CO_3}$ and $\gamma^{L}_{UO_2^{2+}} / \gamma^{L}_{Ca^{2+}}$ are taken as unity, K_{UO_2} is depended on α. Since total uranium dissolved in solution ($M^{L}_{UO_2,T}$) is:

$$M^{T}_{UO_2,T} = M^{L}_{UO_2^{2+}} + M^{L}_{UO_2CO_3^0} + M^{L}_{UO_2(CO_3)_2^{2-}} + M^{L}_{UO_2(CO_3)_3^{4-}}$$
$$= (1+\alpha) M^{L}_{UO_2^{2+}} , \quad (5)$$

where, the value of α is given:

$$\alpha = K_1 \cdot a^{L}_{CO_3^{2-}} + K_2 \cdot (a^{L}_{CO_3^{2-}})^2 + K_3 \cdot (a^{L}_{CO_3^{2-}})^3 \quad (6)$$

Then, equation (4) can be re-written:

$$K_{UO_2} \cong \frac{1}{1 + \{K_1 \cdot a^{L}_{CO_3^{2-}} + K_2 \cdot (a^{L}_{CO_3^{2-}})^2 + K_3 \cdot (a^{L}_{CO_3^{2-}})^3\}} \cdot K^{T}_{UO_2} \quad (7)$$

It is seen that the distribution coefficient of uranium, therefore, is a function of carbonate ion activity.

Based on the equation (7), the relation between K_{UO_2} and $a^{L}_{CO_3^{2-}}$ shows a negative correlation with the slope = −1 when the value of $\alpha = K_1 \cdot a^{L}_{CO_3^{2-}}$ or $UO_2CO_3^0$ is a dominant species in solution. Moreover, the slope = −2 or −3 is produced in case of $UO_2(CO_3)_2^{2-}$ or $UO_2(CO_3)_3^{4-}$ is dominant, respectively, in solution.

We superimpose the modeled slopes of −1 and −2 from equation (7) over the reported distribution coefficient values (Fig. 4) and is shown in Fig. 5. The compiled-data of distribution coefficients seem in agreement with the slope = −1. It is suggested that $UO_2CO_3^0$ maybe a main species in incubated-seawater when we consider that uranium incorporation follows a cation mode. However, the data from individual experiments are somewhat scattered. The trend is still un-clarified yet, hence advanced investigation is necessary for clarifying the trend.

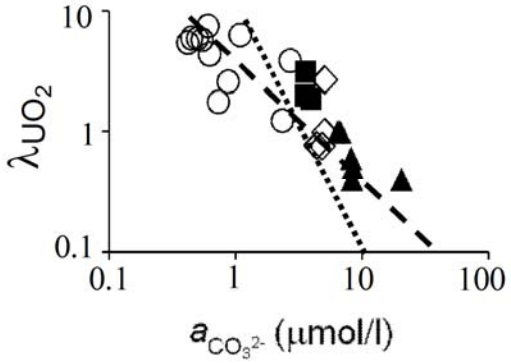

Figure 5: Distribution coefficient of uranium (λUO_2) plotted against the carbonate ion activity (aCO_3^{2-}). The slopes of ..... = −2, and — — = −1 (see text).

Anion hypothesis

Reaction: $CaCO_3 + UO_2(CO_3)_2^{2-} \Leftrightarrow CaUO_2(CO_3)_2 + CO_3^{2-}$

A uranyl carbonate ion (charge = −2) from solution substitutes for a same charge of carbonate ion from $CaCO_3$ phase. In this system, contribution from UO_2^{2+} is neglected and $M^{L}_{UO_2,T}$ is written:

$$M^{T}_{UO_2,T} = M^{L}_{UO_2CO_3^0} + M^{L}_{UO_2(CO_3)_2^{2-}} + M^{L}_{UO_2(CO_3)_3^{4-}}$$
$$= M^{L}_{UO_2(CO_3)_2^{2-}} \cdot \left\{ \frac{1}{\beta_2 \cdot a^{L}_{CO_3^{2-}}} + 1 + \beta_3 \cdot a^{L}_{CO_3^{2-}} \right\} \quad (8)$$

where β_2 denotes a stability constant of $UO_2(CO_3)_2^{2-}$ formation from $UO_2CO_3^0$ and β_2 represents a stability constant of $UO_2(CO_3)_3^{4-}$ formation from $UO_2(CO_3)_2^{2-}$. From equation (8), the abundance of $M^{L}_{UO_2(CO_3)_2^{2-}}$ relatives to the total dissolved uranium is:

$$\frac{M^{L}_{UO_2(CO_3)_2^{2-}}}{M^{L}_{UO_2,T}} = \frac{1}{\left\{ \frac{1}{\beta_2 \cdot a^{L}_{CO_3^{2-}}} + 1 + \beta_3 \cdot a^{L}_{CO_3^{2-}} \right\}} \quad (9)$$

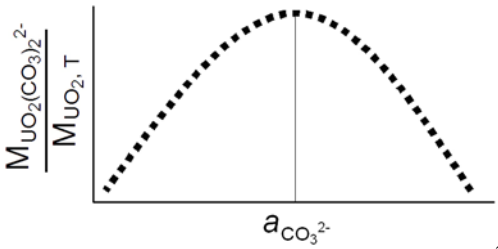

Figure 6: The relative abundance of $UO_2(CO_3)_2^{2-}$ plotted theoretically against the carbonate ion activity (aCO_3^{2-}).

Fig. 6 illustrates a conceptual plot of the relation between relative abundance of $UO_2(CO_3)_2^{2-}$ and carbonate ion activity in the solution. Vertical line in the middle denotes the critical value of carbonate ion activity. Around this vertical line, $UO_2(CO_3)_2^{2-}$ is considered to be a dominant species in solution. Relative abundance of $UO_2(CO_3)_2^{2-}$ is controlled by the equilibrium relation with $UO_2CO_3^0$ at below (i.e. slope = 1) or $UO_2(CO_3)_3^{4-}$ at above the critical value (i.e. slope = –1).

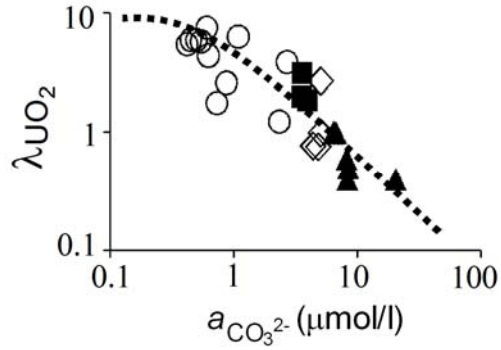

Figure 7: Distribution coefficient of uranium (λUO_2) plotted against the carbonate ion activity (aCO_3^{2-}). The slope of ..... = –1 (see text).

We superimpose the area of slope = –1 of Fig. 6 on the distribution coefficient values (Fig. 4) and is shown in Fig. 7. The entire data of the distribution coefficient of uranium lie within the slope = –1. It may be possible that $UO_2(CO_3)_3^{4-}$ is a dominant species in incubated-seawater when we consider that uranium incorporation as an anion mode.

At present, mode of uranium incorporation into coral skeletons remains unclear. Both candidates (i.e. cation and anion modes) seem valid, yet debatable. More detail studies on the distribution coefficient of uranium are significantly required to provide precise data for clarifying the mode of incorporation.

Using nearshore macrobenthos as environmental indicators adjacent to a major navigational inlet: Port Everglades inlet, Florida

J. A. Craft

Coastal Planning & Engineering, Inc., 2481 N.W. Boca Raton Blvd., Boca Raton, FL, 33431, USA

Abstract. The reefs off Broward County, Florida, USA, lie near the northernmost limits of tropical coral reefs, are non-accreting, and have long been affected by human influences including land-based sources of pollution. Port Everglades, a major industrial shipping port, is a likely source of many anthropogenic contaminants, which are discharged in an effluent plume that sweeps over the coastal reef. The results of two nearshore reef studies were examined here to determine if the inlet effluent plume produces a water quality gradient and associated biological gradient, and if any biological indicators of water quality can be determined. Macrobenthos cover at 33 sites was assessed from Port Everglades inlet south to the Broward County line. Results showed macroalgae abundance significantly increases with proximity to Port Everglades inlet. In addition, water quality data clearly illustrate a low-salinity wedge being discharged from the inlet at low tide, as well as increased levels of nutrients around the mouth of the inlet. These results suggest that Port Everglades is a probable source of coastal pollution that may be causing localized increases in algal abundance that can be detrimental to the benthic ecology of the surrounding nearshore reef.

Key words: land-based pollution, effluent, indicators, coral reefs

Introduction

Coral reefs are used around the world for recreation, food, a source of income, and storm protection. Our lack of understanding of reef ecology and the effects humans have on reefs has taken a toll on these diverse ecosystems. In order to conserve remaining reef systems, proper sensitive and quantifiable biological indicators need to be developed for detection of impacts to reef systems, which can be used on a wide scale.

Monitoring and assessment tools that diagnose coral reef community responses to threats are critical to the management of these ecosystems. Corals themselves are extremely sensitive animals and require a narrow range of environmental conditions in order to thrive. However, corals are slow-growing and may take years to show damage from pollutants. Furthermore, coral growth rates themselves are poor indicators of reef health because growth rates often initially increase with nutrient dumping and land run-off (Koop et al. 2001; Wittenberg and Hunte 1992). Thus, other, more dynamic, taxonomic groups with shorter turnover times, e.g., algae and sponges, may express the effects of pollutants on a reef site in a time frame more feasible for study.

Areas of high nutrient addition often experience increased algal growth rates, which can be detrimental to corals, either by competition for growth and recruitment space or by blocking vital sunlight from reaching the coral (Marszalek 1981; Steneck 1997). High sedimentation, eutrophication, and overfishing of reefs may also reduce the settlement and recruitment of grazers, thereby promoting higher algal cover (Wittenberg and Hunte, 1992; Richmond et al. 2007). Reefs degraded by nutrient over-enrichment often exhibit "phase shifts" from abundant coral to abundant macroalgae (McCrook 1999; Szmant 2002). These observations may be used as early warning signals of reef health degradation.

Heterotrophic sponges may also represent an early warning signal for organic pollution of coral reefs (Wilkinson and Cheshire 1990). Evidence exists that sponge biomass is higher in nutrient-rich waters compared to oligotrophic waters (Wilkinson 1987; Wilkinson and Cheshire 1990). Tomascik and Sander (1985) found the east coast of Barbados, which experiences strong oceanic influences, has a significantly lower biomass of sponges compared to the west side of the island, which is exposed to high levels of nutrients from anthropogenic discharge. Aerts (1998) found that sponges overgrow corals to a greater degree where coral cover is low, suggesting that dying or degraded reefs with reduced living coral

cover may be susceptible to increased overgrowth by sponges. These studies suggests that sponge abundance and biomass are related to nutrient availability, water quality, and overall reef health, and have implications for coral reef impact studies and monitoring.

In Broward County, Florida, USA, Port Everglades may be a source of many anthropogenic contaminants, including nutrients and other pollutants carried in freshwater from coastal runoff, which extend in an ebb-tidal plume that sweeps over the adjacent coastal reef (Fig. 1). What direct effects these contaminants may have on adjacent reef life is hypothesized; however, direct studies on the effects of effluent from Port Everglades inlet are limited. This paper examines macrobenthic data collected from two nearshore community assessment studies in Broward County. These data are used to evaluate the effects of proximity of reef biota to a major navigational inlet and identify potential bioindicators of stress on the reef system.

Materials and Methods

Monitoring design

Results from two separate studies were combined. The first study (Study 1, Craft 2006) assessed the percent cover of macroalgae and sponge at seven nearshore sites immediately south of Port Everglades inlet**.** Preliminary results from Study 1 indicated that coral abundance within the study area is highly variable, and primarily dictated by variations in substrate type and availability rather than any existing water quality gradients; thus, other, more dynamic taxonomic groups, e.g. macroalgae and sponges, are examined here. Site placement was based on prior water quality surveys and thermograph stations used by Broward County Environmental Protection Department (BCEPD) (BCEPD, 2007). Sites were numbered from south to north, starting at BCEPD Thermograph Station JUL6. Each site consisted of three shore-parallel 30-m transects. A $0.25m^2$ x $0.25m^2$ quadrat was placed every other meter for a total of 45 quadrats per site, and 2.81 m^2 of area surveyed.

Water quality parameters were also measured during Study 1. A YSI data-sonde was used to measure specific conductivity (as a proxy for salinity). The probe was lowered haphazardly within the inlet plume over the general study area. Vertical readings were taken at these locations with the sonde, from surface to bottom in order to observe changes in specific conductivity with depth, implying a gradation in salinity with depth. Water samples were also taken from select areas across the influence of the plume and analyzed for chlorophyll *a* and nutrients: total phosphorus, nitrites and nitrates (NO_2+NO_3), and Total Kjeldahl nitrogen (TKN).

The second study (Study 2) was conducted as a pre-construction survey for the Segment III Broward County Beach Renourishment Project. Twenty-one transects were surveyed south of Port Everglades inlet to the southern Broward County boundary using the Benthic Assessment for Marginal Reefs (BEAMR) method (Lybolt and Baron 2006). A $0.5m^2$ x $0.5m^2$ quadrat was placed every 2.5 meters along a 30-m transect for a total of 12 quadrats per transect, and 3.0 m^2 of area surveyed. Sponge and macroalgae percent cover data were extracted from this data set and combined with data from Study 1 for analysis.

Data analysis

Benthic coverage data were first standardized for amount of hardbottom sampled (i.e. eliminating sediment cover). Data were then fourth-root transformed and compared, using linear regression, against distance from the inlet (latitude; dd.ddd) to determine if trends exist relative to the location of Port Everglades inlet.

Linear regression was also used to examine specific conductivity relative to distance from the inlet, and plotted against latitude (dd.ddd) and depth (m) to create vertical and surface-planar descriptions of the inlet plume and associated salinity "wedge". Chlorophyll *a* measured from grab samples was examined against specific conductivity in the same manner.

Results

Benthic cover

After standardizing for amount of hardbottom sampled, macroalgae cover ranged from 1.4% to 54.0%. Standardized sponge cover ranged from 0.1% to 2.7% (Table 1).

Table 1. Macroalgae and sponge cover (percent) standardized for amount of hardbottom sampled.

Regression results indicate a significant linear trend in macroalgae cover with proximity to the inlet ($p=0.002$; $R^2=0.275$) (Fig. 2). Regression results for sponge cover indicate no significant linear trend in the data exists ($p=0.373$; $R^2=0.027$).

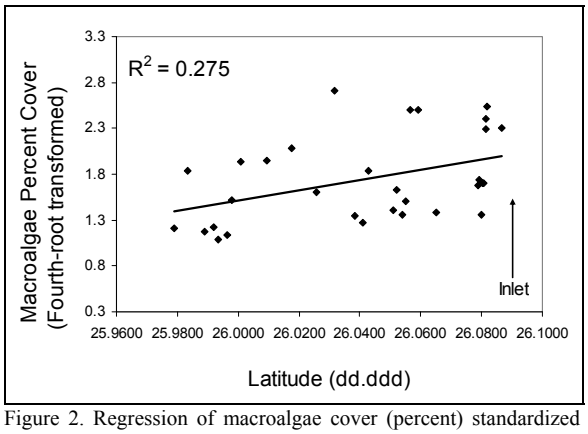

Figure 2. Regression of macroalgae cover (percent) standardized for hardbottom sampled, and fourth-root transformed, against distance from Port Everglades inlet (latitude; dd.ddd).

Water Quality Analysis

Parameters from water grab sample data near the inlet were plotted against latitude to demonstrate surface nutrient levels surrounding the inlet (Table 2; Fig. 3). Peak levels of nutrients can be observed immediately adjacent to the inlet, and dissipate with distance.

Table 2. Nutrient levels measured from grab samples taken at the surface within the inlet plume. *Denotes chlorophyll *a* sample not obtained at that location. Specific conductivity was measured at ~28°C.

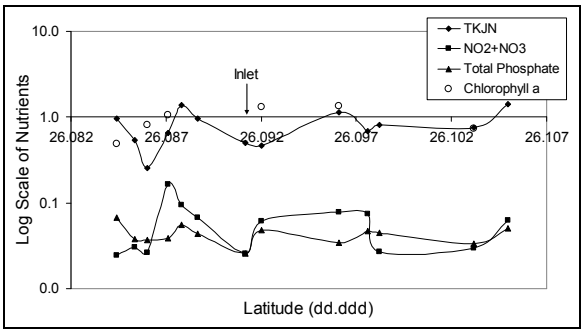

Fig. 3. Nutrient levels measured from plume water grab samples plotted against latitude across the mouth of Port Everglades inlet (log scale).

Figure 4 shows the vertical salinity gradient, or "salt wedge" in the waters immediately surrounding the inlet. Specific conductivity readings of surface water adjacent to the inlet were as low as 37,337 micro-Siemens per centimeter (μScm^{-1}), and increased as depth increased. Average oceanic conductivity ranges from 53,000-58,000 μScm^{-1} (measured between 25°C and 30°C). According to the figure, standard average ocean salinity is reached at approximately 3 m depth.

Figure 5 shows the change in surface salinity with latitude. This figure depicts the extent of the plume at the time of sampling and illustrates that specific conductivity is lowest adjacent to the inlet and increases with distance from the inlet to the north and south.

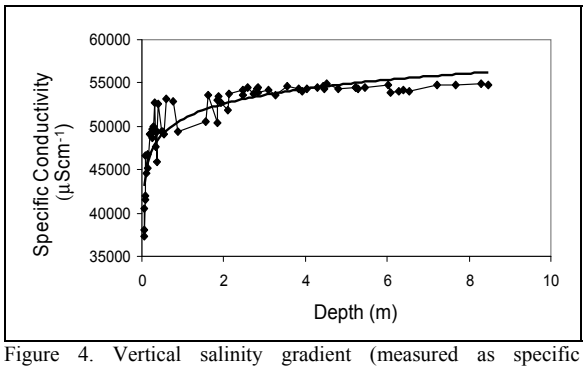

Figure 4. Vertical salinity gradient (measured as specific conductivity) across the mouth of Port Everglades inlet. Standard oceanic salinity is reached at approximately 3 m depth.

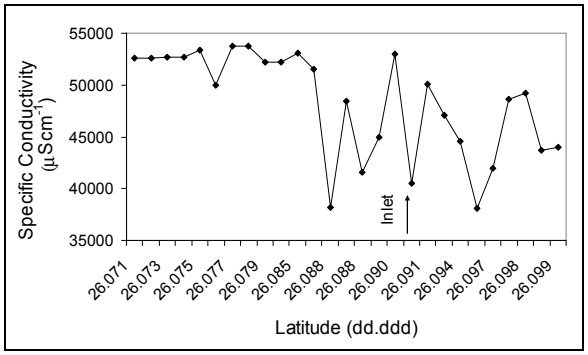

Figure 5. Change in surface salinity (measured as specific conductivity) surrounding the mouth of Port Everglades inlet with latitude. Salinity is lowest directly out from the inlet.

Regression results show that specific conductivity significantly decreases with proximity to the inlet ($p=0.0005$; $R^2=0.445$) (Fig. 6). Chlorophyll *a* was observed to increase with decreasing specific conductivity, though not significantly.

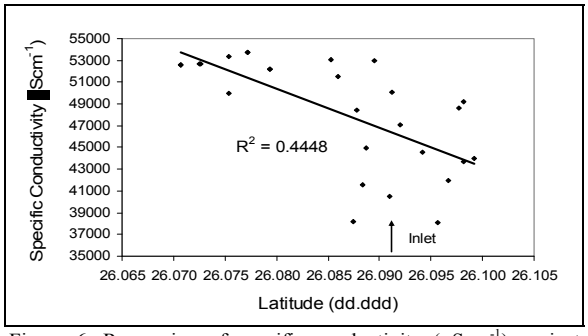

Figure 6. Regression of specific conductivity (μScm^{-1}) against distance from Port Everglades inlet (latitude).

Discussion

Because nutrients and other pollutants coming from the inlet are carried in a plume of lower-salinity water that flows as a surface "wedge" over the surrounding reef area, specific conductivity readings were used as a proxy indicator to map the approximate extent of the plume, both vertically and horizontally. The profile in Fig. 4 suggests that the plume sweeps out over the adjacent reef area at an angle influenced by the existing specific conductivity gradient (i.e. water of lower salinity will move over water of higher salinity). The combination of vertical specific conductivity profile and the general increase in surface specific conductivity with distance from the inlet (Fig. 5) suggest that benthos closer to the inlet and its discharge will be more strongly affected by the effects of lowered salinity. Lower-than-oceanic-salinity water has been proven detrimental to coral health (Linton and Warner 2003). According to Fig. 4, shallow reef areas near the inlet, especially at low tide, would be exposed to lower salinity and plume contaminants, since probe measurements do not reach normal seawater specific conductivity until approximately 3 m depth.

Abundance of inorganic nutrients in nearshore environments, particularly coral reefs, has a potentially strong influence on phytoplankton communities and trophic processes there, and has thus been recognized as a critical aspect of coastal management (Devlin et al. 2000). Dissolved nutrients in the marine environment are rapidly converted to particulate form and in turn rapidly recycled. Because of this, planktonic algae, specifically their chlorophyll *a*, have been used as a proxy indicator of nutrient abundance when monitoring water quality (Devlin et al. 1999; Linton and Warner 2003). Fig. 3 shows nutrient and chlorophyll *a* levels from grab samples highest around the mouth of the inlet, and chlorophyll *a* increased with decreasing specific conductivity (although the relationship between chlorophyll *a* and specific conductivity was not found to be significant). As specific conductivity was significantly correlated with proximity to the inlet, it appears that increased chlorophyll levels may be linked to low-salinity water, as well as increased levels of nutrients, being discharged from the inlet, although a larger sample size is desired for thorough chlorophyll *a* analysis. Though coral cover appears largely dictated by substrate variability in the nearshore area surrounding Port Everglades, corals growing near the inlet may be at risk of higher stress levels than those further from inlet influence. Heavy concentrations of phytoplankton in the water column over reefs as a result of nutrient addition may increase coral mortality due to competition for light and effected production/respiration (P/R) ratios (Marszalek 1981; Yentsch et al. 2002).

Although sponge cover was not significantly correlated with distance from the inlet, benthic macroalgae significantly increased with proximity to the channel. Water samples from each monitoring site were not obtained for nutrient measurements; however, Fig. 3 suggests that this increase in

macroalgae is due to increased nutrient availability near the inlet. Reefs experiencing nutrient addition often exhibit a shift from abundant coral to abundant macroalgae (McCrook 1999; Szmant 2002).

Although coral cover within the study areas was not significantly correlated with distance from the inlet, nearshore stony coral cover throughout Broward County south of Port Everglades inlet is naturally low, likely due to stochastic events such as hurricanes and tropical storms that frequently bury portions of the nearshore hardbottom (Prekel et al. 2008). Thus the coral-depauperate area of the nearshore benthic habitat in Broward County should be treated as a reef habitat continually under stress from natural stochastic events, as well as pollution, coastal construction and other physical impacts, and managed appropriately.

When examining the extent of the inlet plume and its influence on the surrounding benthic area, specific conductivity was found to be a reliable proxy for delineating the extent of inlet effluent plume, and abundance of benthic macroalgae and chlorophyll may be indicators of nutrient addition to the area.

It is the conclusion of these studies that Port Everglades is a source of low-salinity water, and may be discharging pollutants that can cause localized increases in phytoplankton and macroalgae abundance, all of which may be detrimental to the benthic ecology of the surrounding nearshore reef. However, lack of long-term records of variations in water quality and plume distribution make concrete determinations difficult. It is suggested here that continued benthic monitoring, as well as further water quality monitoring in proximity to Port Everglades, are needed in order to establish a more thorough analysis of the effects of inlet discharge on the surrounding nearshore reef habitat, and to make accurate predictions of changes to the habitat in the face of on-going coastal impacts.

Coral rare earth element tracers of terrestrial exposure in nearshore corals of the Great Barrier Reef

S. D. Jupiter[1,2]

1) U. of Queensland, ARC Centre of Excellence for Coral Reef Studies, Brisbane, QLD 4072, Australia
2) U. C. Santa Cruz, Dept. of Ecology and Evolutionary Biology, Santa Cruz, CA 95064, USA

Abstract. Rare earth element and yttrium (REY) concentrations were measured from two nearshore *Porites* sp. corals collected from Round Top Is. and Keswick Is., at 5 km and 32 km offshore from Mackay, Queensland, on the southern Great Barrier Reef, Australia. The REY patterns from the Round Top coral differed from the Keswick coral in 5 respects: (1) greater REY concentrations; (2) preferentially enriched light rare earth elements (LREEs); (3) reduced slope across the heavy rare earth elements (HREEs); (4) more negative cerium (Ce) anomaly; and (5) lower yttrium (Y) to holmium (Ho) ratios. These patterns suggest greater terrestrial exposure and higher biological productivity at Round Top Is. Total abundance of REY in both corals increased over time between 1950 and 2002. The rate of increase at Round Top Is. was 3-fold greater than at Keswick Is., thus the innermost site was likely more influenced by weathering from rapid agricultural expansion in the adjacent Pioneer River catchment. The Y/Ho ratio decreased over time in both corals, but as the coral values were substantially higher than ambient seawater, more research is suggested to identify the cause.

Key words: Rare earth elements, yttrium, *Porites*, Great Barrier Reef

Introduction

Concentrations of rare earth elements and yttrium (REY) in coastal corals are good geochemical tracers of freshwater runoff and/or chemical weathering of continental crust because they are: (1) incorporated into coral lattices in close proportion to ambient seawater concentrations (Sholkovitz and Shen 1995); and (2) fractionated differentially in shales, river water and seawater (Elderfield et al. 1990). REY can be measured independently, or together in series, to investigate patterns that may indicate sources from local geology or land use (Lawrence et al. 2006a). Yet, the geochemical pathways from riverine transport of REY to incorporation within coral skeletons are not well studied, largely because instruments that can measure aqueous concentrations of yttrium and the monoisotopic REE with precision have only recently become available (Nozaki et al. 1997; Lawrence et al. 2006b).

River discharge is the main source of marine REY concentrations in nearshore waters (Byrne and Sholkovitz 1996). REY come from weathered topsoil and are transported in catchment waterways attached to colloidal particles within the 0.45μm fraction of the suspended sediment load (Byrne and Sholkovitz 1996). A large proportion of REY is removed in the estuarine mixing zone due to flocculation of iron-organic colloids at low salinities (Sholkovitz 1995), although large increases in REY abundances between ~5 to 10 ppt probably reflect REY release from river particles (Lawrence and Kamber 2006). Fractionation of the freshwater REY pattern also occurs within the mixing zone: light rare earth elements (LREEs) become more depleted relative to heavy rare earths (HREEs); Y fractionates relative to holmium (Ho), and a positive lanthanum (La) anomaly develops relative to its pattern in shale (Lawrence and Kamber 2006).

To identify potential terrestrial sources in marine REY, the data are typically normalized to a sediment or shale to remove the natural "saw-tooth" distribution of absolute abundances and to describe the pattern relative to a continental source (Byrne and Sholkovitz 1996). Elemental anomalies within normalized pattern, defined as departures from a smooth line predicted by extrapolation from neighboring elements (Sholkovitz 1995), can be used as "fingerprints" of biological and physical processes and/or provenance features (Akagi et al. 2004; Lawrence et al. 2006a). For example, *Porites* corals living adjacent to a soft waste dump and creek delivering runoff from an open-cut mine on Misima Island, Papua New Guinea (PNG) had positive middle rare earth element (MREE) anomalies that closely resembled those from Sepik River water (Fallon et al. 2002), suggesting that provenance information from a strong source can be preserved through the estuarine mixing zone.

In this study, REY patterns were measured from nearshore corals of the south-central Great Barrier

Reef (GBR), collected at 5 and 32 km offshore from the Pioneer River mouth and city of Mackay (Queensland, Australia). Since European settlement in 1865, there has been substantial land clearing both historically and in recent decades to support a rapidly expanding sugarcane industry (Jupiter and Marion 2008). Anomalies within REY patterns were examined to detect spatial differences in terrestrial exposure, while temporal changes in total REY load and Y/Ho ratios since the 1950s were measured to assess potential linkages to catchment land cover change.

Material and Methods

Sample preparation

Two cores (RTF, KIA) were collected from massive *Porites* colonies at reefs fringing Round Top Is. (5 km offshore) and Keswick Island (32 km offshore). Density bands from x-radiographs were used to identify years in slabs cut from each core, from which bulk samples were drilled from annual coral growth periods spanning years between 1950 and 2002. For each core, 3-5 consecutive years were analyzed from each decade. For each annual sample, approximately 5-15 µg of coral powder was diluted by 1000 with >18.2 MΩ water, HNO_3 was added to a total concentration of 2%, samples were left to digest overnight, and all solutions, including blanks, were spiked with 2 ppb of internal standard (indium (In), rhenium (Re), bismuth (Bi)).

Solution ICP-MS analyses

All samples were analyzed at the University of Queensland on a Thermo X-Series inductively-coupled mass spectrometer (ICP-MS). For instrument specifications, sensitivity and operating power, see Lawrence et al. (2006a) and Lawrence and Kamber (2006). Dilutions of USGS dolerite W-2, Mud of Queensland (MUQ; Kamber et al. 2005), and JCp-1 coral reference material (collected in 1999 from Ishigaki Island, Okinawa, Japan) were measured simultaneously with the samples for machine calibration. All REY (except promethium (Pm), which does not exist naturally in measurable concentrations; Byrne and Sholkovitz 1996), zircon (Zr) and the appropriate suite of interfering isotopes were measured. All data were corrected for drift (internal and external), oxide interferences (for europium (Eu) and heavier elements), and dilution factors.

Statistical analyses and anomaly calculations

A principal components analysis (PCA) was performed using a VARIMAX rotation to compare coral REY patterns with seawater, river water and sediment. Mean coral REY from RTF and KIA (over all years analyzed) were compared with REY data from MUQ and water samples collected from: Pioneer River mouth and estuary (Lawrence et al. 2006a); Coral Sea (Zhang and Nozaki 1996); and streams draining different regions of the Pioneer catchment (Lawrence et al. 2006a) (Fig. 1a). All REY abundances were scaled to the same value of samarium (Sm), for which anomalies are not expected, and Eu was excluded from the PCA because isobaric interference of BaO during ICP-MS analysis resulted in unreliable measurements of Eu from the Pioneer stream water samples (Lawrence et al. 2006a).

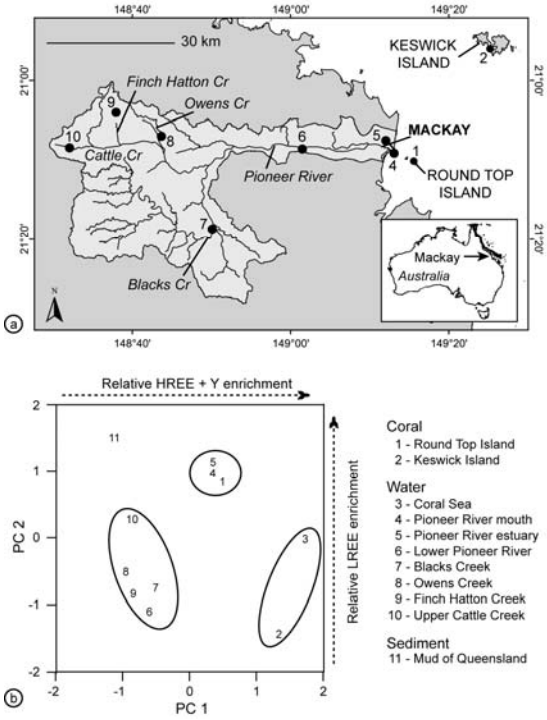

Figure 1: (a) Locations of coral core and water sample collection sites in and adjacent to the Pioneer River catchment. Inset depicts the location of Mackay within Australia. (b) Scaled REY data from coral, water and sediment samples plotted against principal components PC1 and PC2. Dashed arrows indicate directional enrichments of different groups of elements.

For assessment of deviations from the typical seawater pattern as indicators of terrestrial influence, mean coral sample REY concentrations (ppb) were normalized to those from terrestrial sediment (MUQ). To compare Mackay coral REY patterns to records from other studies, published coral REE abundances were also normalized to MUQ. The Ce anomaly was calculated using an equation from Lawrence et al. (2006b), Ce_n/Ce_n^*, where n refers to the shale-normalized abundances of Ce, praseodymium (Pr) and neodymium (Nd):

$$Ce_n^* = Pr_n * (Pr_n/Nd_n)$$

Mean differences in Ce anomalies between RTF and KIA were assessed with two-sample t-tests, after using Cochran's test to assess homoscedasticity. The ratio Lu_n/Er_n was calculated to evaluate the slope of HREE, where n refers to the shale-normalized abundances of lutetium (Lu) and erbium (Er). Because RTF and KIA had unequal variances in Lu_n/Er_n ratios, a two sample t-test with unequal variances was used to determine significance.

Multiple regressions were performed to assess changes in total REY and Y/Ho ratios from each core over time, using year and Pioneer River discharge as the independent variables. Correlations of Zr and Y/Ho ratios were checked for each core to assess detrital contamination, which would lower the Y/Ho mass ratio closer to shale values (~26) and elevate concentrations of terrestrially derived elements such as Zr (Webb and Kamber 2000). All statistical analyses were done with SYSTAT v.10.2 software.

Results

General Mackay REY patterns

When the scaled REY data were ordinated along the first two principal components, which explained 67.9% and 20.8% of the total variance respectively, the data from the most inshore coral (RTF) clustered tightly with water samples from the Pioneer River mouth and estuary (Fig. 1b). Coastal seawater, the RTF coral and terrestrial sediment (MUQ) all had high positive values along principal component 2, which are largely explained by differences in scaled LREE abundances. By contrast, the coral from further offshore (KIA) and the offshore seawater sample from the Coral Sea, had high positive values along principal component 1, which are largely explained by differences in scaled middle rare earth element (MREE) and HREE abundances. The large differences in scaled Y abundances also contribute to principle component 2, with scaled abundances of Y strongly mirroring a gradient of terrestrial influence (MUQ < Pioneer catchment streams < Pioneer River mouth < RTF < KIA < Coral Sea).

When just the coral samples were compared, RTF differed from KIA in five main respects. RTF had: (1) greater total REY abundance; (2) preferential enrichment of LREEs ; (3) flatter HREE patterns; (4) more negative Ce anomalies; and (5) smaller Y/Ho ratios (Table 1, Fig. 2). REY abundances from RTF were ~2-5 times higher than REY abundances from KIA, while LREE were preferentially enriched in RTF relative to KIA. Although shale-normalized REY from both cores were HREE enriched, RTF was less so relative to KIA, as indicated by a significantly greater (= higher slope) mean Lu_n/Er_n ratio in KIA (1.67) than in RTF (1.11) ($t = 17.41$, $df = 43$, $p < 0.001$). The mean Ce anomaly (0.502) for the RTF core was significantly lower than that (0.610) from KIA samples ($t = 6.86$, $df = 51$, $p < 0.001$). The mean Y/Ho ratio (67.3) for RTF was less than half of the mean Y/Ho (142.6) for KIA. Because there was no significant negative relationship between Zr with Y/Ho for either RTF or KIA ($r = 0.370$, $p > 0.05$ and $r = 0.045$, $p > 0.10$, respectively), these differences were not likely due to terrigenous contamination.

Temporal change

There were two major trends in the coral REY over time in both the RTF and KIA corals: (1) increased total REY; and (2) decreased Y/Ho ratios (Fig. 3a). The rate of increase in total REY abundance was approximately three times greater in RTF than in KIA, and was significantly related to both year and Pioneer River discharge: when combined they explained 49% and 46% of the total variance at Round Top and Keswick, respectively. The significance of the change in the total inshore coral REY load was more affected by river discharge at Round Top Island (partial $r^2 = 0.365$, $p < 0.002$) than at Keswick Island (partial $r^2 = 0.134$, $p < 0.025$).

The second temporal pattern in both coral records was a significant decrease of Y/Ho ratios over time, which occurred at similar rates at Round Top and Keswick islands (Fig 3b). In RTF, the trend was significantly related to year ($p < 0.001$) but not to discharge ($p < 0.059$), and together they explained 77% of the total variance. By contrast, Pioneer discharge had a more pronounced effect on the variability of Y/Ho in KIA: both year ($p < 0.002$) and discharge ($p < 0.035$) were negatively correlated with Y/Ho, but together they explained only 42% of the total variance.

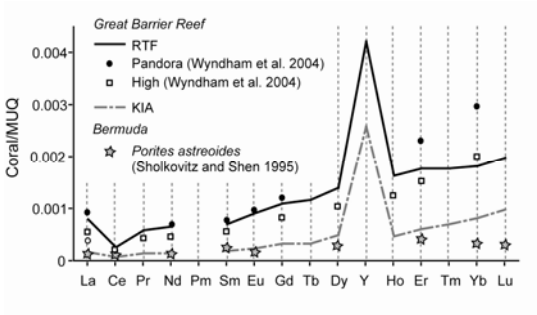

Figure 2: (a) Mean MUQ-normalized patterns in corals from Mackay (RTF: black lines; KIA: grey dashed lines) compared with other inshore GBR records (Pandora: black circles; High: white squares) and a Bermuda coral (stars).

Discussion

The presence of all of the typical marine features (La anomaly, Ce anomaly, Y/Ho fractionation, and HREE > LREE) in MUQ-normalized REY patterns from

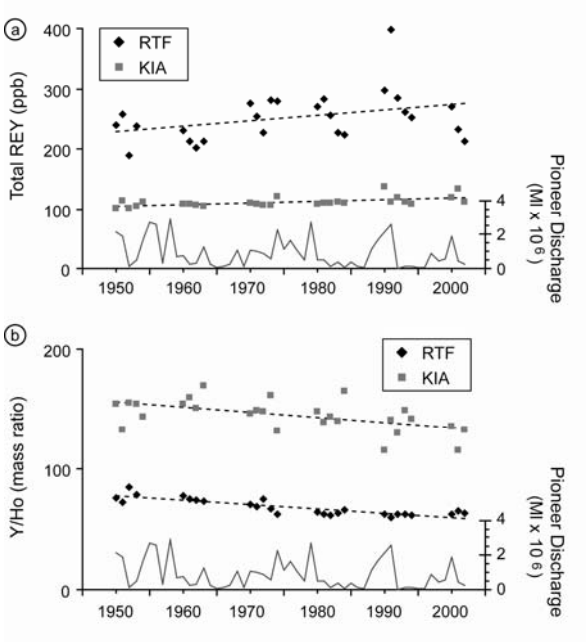

Figure 3: Temporal trends in (a) total REY concentration and (b) Y/Ho ratios between 1950 and 2002 for RTF (black diamond) and KIA (grey squares). Annual Pioneer River discharge (in megaliters) is shown with each plot.

both Mackay corals supports the assertion by previous authors that corals incorporate REY in proportion to ambient seawater concentrations (Sholkovitz and Shen 1995). However, the subtle differences in patterns between corals from Round Top and Keswick reefs likely indicate differential exposure to Pioneer River runoff and consequent differences in productivity.

The MUQ-normalized REY patterns and magnitudes from RTF were in strong agreement with other inshore GBR corals (Fig. 2) (Wyndham et al. 2004). By contrast, KIA had lower MUQ-normalized magnitudes that were similar to values from an offshore GBR reef (Wyndham et al. 2004) and values from a *Porites astreoides* collected from Bermuda (Sholkovitz and Shen 1995), suggesting reduced terrestrial influences at these sites. The underlying steady but small increase in total REY abundance over time at both sites suggests diffuse inputs of REY, possibly from greater catchment erosion coincident with agricultural expansion. Increases in REY values were most notable at Keswick in years with large floods, when plumes were more likely to reach the vicinity of the island.

LREE enrichment in the Round Top coral probably relates to greater terrestrial influence, as LREEs may be more readily mobilized by weathering than HREEs (Nesbitt et al. 1990). LREE enrichment in corals is often associated with river runoff: for example, Shioya-wan Bay (Okinawa, Japan), which receives runoff from the Taiho-o-kawa River, has flatter REY patterns (caused by LREE enrichment) and higher magnitudes of total REE in seawater and corals (including *Porites lutea*) than Sesoko-jima Island, which is distant from riverine sources (Akagi et al. 2004). When corals are sampled seasonally, LREE enrichments appear to coincide with large flood events (Wyndham et al. 2004).

The difference in the relative slopes of HREE between RTF and KIA may also be the product of terrestrial exposure. Like the water sample from the Coral Sea, the KIA coral had relative enrichments in scaled HREE abundances. While HREE enrichments are typical features of normalized oceanic seawater patterns, relative depletions in coastal waters can result from fluvial discharge, since inputs from major rivers are usually HREE depleted relative to shale (Goldstein and Jacobsen 1988). Alternatively, the flatter HREE patterns at Round Top Island may reflect differences in productivity between the two sites: Wyndham et al. (2004) noted seasonal HREE depletion in high resolution records of inshore GBR corals that they attributed to scavenging by organic (or organically coated) particles created through biological activity. Evidence of summer *Trichodesmium* blooms in the Pioneer River plume inshore from Keswick Island (Rohde et al. 2006) suggest there may be substantial differences in biological activity between the sites.

Table 1. Mean concentrations of REY in RTF, KIA, JCp-1, W-2 and MUQ. All values are in ppb, except detection limits (DL), which are in ppt (parts per trillion).

Differences in Ce anomalies between the two sites may also be linked to site-specific differences in biological activity. The more negative Ce anomaly from Round Top agrees with other coral (Wyndham et al. 2004) and seawater records (Nozaki et al. 2000) showing stronger Ce anomalies in coastal regions than offshore. Wyndham et al. (2004) found strong correlations between the timing of spring-summer peaks in both Mn/Ca and Ce anomalies from inshore corals. Since Ce oxidation is probably coupled with microbially-mediated Mn oxidation, Wyndham et al. (2004) suggested that Ce oxidation increased during periods of high solar radiation and temperature, and after floods, all of which increase the abundance of oxidizing bacteria.

Explanations for Y/Ho values observed in the Mackay corals may be more complex. Due to differing surface complex stabilities, Ho is scavenged approximately twice as fast as Y within the estuarine mixing zone (Bau 1996), resulting in a superchondritic marine Y/Ho mass ratio that typically varies between ~40 and 77 (Nozaki et al. 1997; Lawrence and Kamber 2006). If corals incorporate REY in proportion to seawater concentrations, and if coastal seawater REY patterns are intermediate between riverine and offshore sites, then coastal corals would be more likely to have lower Y/Ho ratios than corals from further offshore. In relative terms, the data supported this hypothesis, but in terms of absolute Y/Ho values, the coral values may not reflect surface seawater conditions. While the Y/Ho ratio (40.5) in Pioneer River mouth seawater was at the lower end of seawater range, the mean RTF Y/Ho value (67.3) was near the upper end of the range, suggesting that: (1) the distribution coefficients for Y and Ho incorporation into coral may vary, as observed for REE measured from Bermuda corals (Sholkovitz and Shen 1995); or (2) seawater fractionation between Y and Ho may change between the river mouth and sites further offshore. The mean Y/Ho value (142.6) for KIA, while similar to that (150.8) from the reference coral JCp-1, was nearly double the upper measurements of seawater Y/Ho. Such discrepancies in coral Y/Ho values compared to their local seawater Y/Ho ratios led Webb and Kamber (2000) to suggest that, in some cases, modern microbialites (with average Y/Ho = 56.1) may actually be a better proxy for seawater REY than skeletal carbonates. These results suggest that while trends of decreasing Y/Ho may be related to increasing catchment weathering and/or exposure to freshwater, further studies are needed to better determine how the elements are incorporated into coral skeletons.

Abstract: Coral reefs are under severe threat from changing climate, yet little is known about how environmental variables affect the establishment and development of coral symbiosis. Here, we use a coral larval model to test whether temperature affects the establishment and development of symbiosis using three different strains of algal symbionts (zooxanthellae) with contrasting thermal tolerance. We also compare the growth of these clades within the larval host, *Acropora intermedia*, and follow the survival of three different larval holobionts under three different temperatures (26, 30 and 34°C). Initial rates of infection were influenced by temperature in two of the three clades: in clade C9b infection rates peaked at 30°C, while in clade A6 infection rates declined with increasing temperature. Infection by clade C1 zooxanthellae was uniformly low. The thermal tolerance of the zooxanthellae did not appear to influence survival of the holobiont, however, at high temperature larvae with high densities of zooxanthellae had lower survival, suggesting zooxanthellae may be an added burden to larvae when under stress.

Keywords: coral reefs, climate change, larval ecology, reproductive biology, symbiosis

Introduction

Coral reefs are under severe threat from many sources, including rising sea-surface temperature caused by climate change (Hughes et al. 2003). A major concern is that the accelerating rate of environmental change could exceed the capacity of coral species to acclimate or adapt (Hoegh-Guldberg et al. 2007). Corals are a symbiosis between the animal host and micro-algae from the genus *Symbiodinium*. While the association is in most cases highly specific, with a given coral species associating predominantly with a single sub-clade (Knowlton and Rohwer 2003), some species associate with more than one strain and multiple strains can occur within a single colony (Rowan and Knowlton 1995, van Oppen et al. 2001). Under stress, such as high sea water temperature, the assocation can break down with a consequent loss of the algal symbionts. This process is known as coral bleaching, and can lead to the death of the coral host (Baird and Marshall 2002). Because symbiotic strains differ considerably in physiological characteristics, such as tolerance to high temperatures (Bhagooli and Hidaka 2003, Rowan 2004), a switch from a thermally susceptible to a tolerant strain is one mechanism by which corals may respond to rising seawater temperature associated with climate change (Buddemeier and Fautin 1993). This mechanism has received considerable attention in the recent literature (Baker et al. 2004), however, experimental support for it is inconclusive. For example, while there is some evidence that the identity of the symbiont can affect the physiology of the host (Little et al. 2004), it has only recently been demonstrated that heat tolerant symbionts can increase the tolerance of the host (Berkelmans and van Oppen 2006). Similarly, while a shift in the dominant clade of zooxanthellae within coral colonies has been documented following stress, such as disease (Toller et al. 2001), and transplantation (Baker 2001) there is no direct evidence to show that this change had been induced by a change in temperature nor that these shifts increase the fitness of the host (Hoegh-Guldberg et al. 2002, Douglas 2003). Furthermore, there is no evidence to show that scleractinian corals can acquire novel, and superior, symbiont clades from the

environment (Sotka and Thacker 2005). The appeal of the adaptive bleaching hypothesis is that it provides a mechanism by which corals can adjust to stress as soon as change is induced rather than over generations, as would be required via adaptation. However, changes in the composition of a species compliment of *Symbiodinium* are most likely to occur between generations at least in those species which do not inherit zooxanthellae from the parents (LaJeunesse et al. 2004). For most coral species, initial infection occurs as larvae or early juveniles, which appear, at least initially, to be much less specific in their choice of algal partner (Baird et al. 2007). Consequently, each larval recruitment event provides the opportunity for novel symbioses to be established.

The absence of zooxanthellae in oocytes of most broadcast spawning corals providing an opportunity to manipulate symbioses to explore the effects of different symbionts on the performance of the holoboint. Larvae which lack symbionts can be readily infected with many different species of symbionts under experimental conditions (van Oppen 2001, Weis et al. 2001). Consequently, it is possible to compare symbiotic and non-symbiotic individuals of the same species and to readily control the identity of both the host and the symbiont. Control over the make-up of the association is not possible in adults, because even completely bleached adults still contain residual densities of symbionts (Jones 2008) and it is yet to be established whether adults can acquire novel strains from the external environment (Hoegh-Guldberg et al. 2002).

Here, we use the coral larval model to test whether temperature effects the establishment of zooxanthella strains of contrasting thermal tolerance in larvae of the coral *Acropora intermedia*. Next we explore how the growth rate of zooxanthellae within the host is affected by temperature and finally we explore survival of three holobionts under different temperatures.

Material and Methods

We first tested the photo-physiological response of four strains of *Symbiodinium* to temperature (Fig. 1). *Symbiodinium* were isolated from four different cnidarian hosts following Yakovleva and Hidaka (2004) and identified following using internal transcribed spacer 2 (ITS2) region amplified for DGGE following Lajeunesse (2002). The host and the corresponding strains were *Seriatopora caliendrum* (C1) *Acropora intermedia* (C3), *Platygyra ryukyuensis* (C9b) and *Tridacna crocera* (A6). Isolated zooxanthellae were placed on Millipore filters and then exposed to four temperature levels, 26, 29, 32 and 34^{o}C, under a moderate light level of 110 µmol photons m^{-2} s^{-1}. A pulse amplitude modulated chlorophyll fluorometer (PAM) was used to asses the maximum quantum yield (20 min dark-adapted F_v/F_m) of zooxanthellae following Bhagooli and Hidaka (2003). Measurements were taken prior to thermal treatment (0h) and then after 6 and 12h.

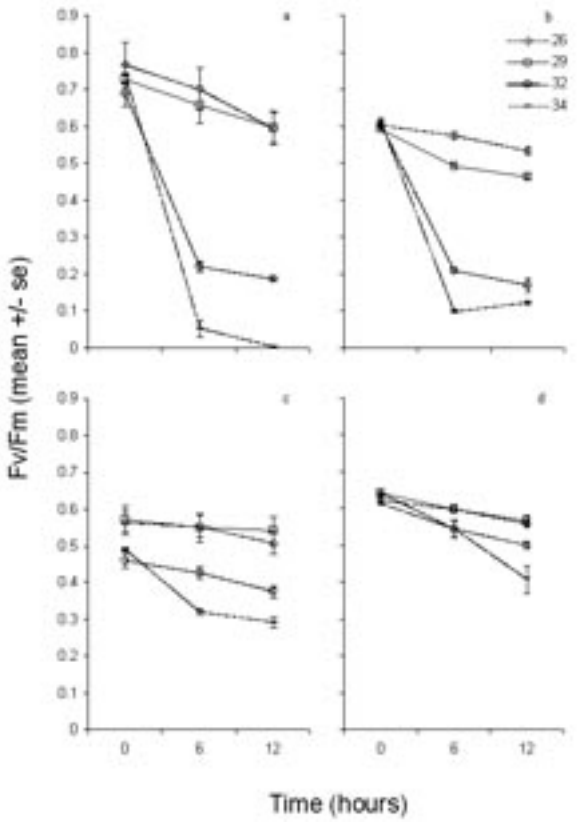

Figure 1. Thermal tolerance in four strains of zooxanthellae (a = C1, b = C3, c = A6, d = C9b).

Next we exposed larvae of *Acropora intermedia* (a species which does not contain zooxanthellae in the oocytes) collected from colonies maintained at the Churaumi Aquaria, Okinawa Japan to freshly isolated batches of three strains of zooxanthellae (all except strain C3) at densities of 4.3 x 10^6 cells per mL^{-1}at three different temperatures 26, 30 and 34C. Larvae were cultured and maintained in 0.2 FSW for three days post-spawning (Baird et al. 2006). Temperatures were maintained using temperature control units (EYELA, Thermister Tempet T-80) and larvae were kept under 110 µmol photons m^{-2} s^{-1} of PAR with a 12:12 h light: dark photoperiod. A sub-sample of 6-8 larvae was removed from each of three replicate jars after 24h and squashed under a coverslip and observed under a fluorescent microscope and the number of zooxanthellae per larva counted. In a second experiment, larvae were infected with zooxanthellae of strains C3, C9b and A6, and 50

larvae placed in 200 ml glass jars at three temperatures, 26, 30 and 32°C and larval survival was followed for 8 d. The density of zooxanthellae at the end of this time was counted to compare the growth rate of strains at each temperature.

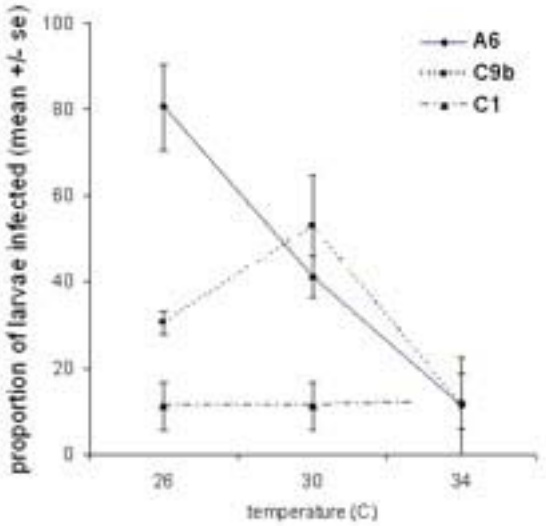

Figure 2. Percentage of *Acropora intermedia* larvae infected by zooxanthellae

Results and Discussion

The four ITS2 types of zooxanthellae clearly exhibited different functional responses to temperature (Fig. 1). Maximum quantum yield (F_v/F_m) was not affected under either 26 or 29°C treatments in any strain (Fig. 1). In strains C3 and C1, F_v/F_m dropped sharply after 6h exposure at 32°C. In contrast a significant decline in F_v/F_m did not occur until 12h at 34°C in strains C9b and A6. The zooxanthellae were consequently ranked in terms of their thermal tolerance as follows: C1 = C3 < A6 = C9b. Also of interest is the wide variation in thermal tolerance among strains of clade C, strengthening the argument that the clade of zooxanthellae is not necessarily an accurate indication of its thermal sensitivity (Toller et al. 2001). Finally, clade A zooxanthellae were both highly infective at ambient temperature, and grew rapidly within the host at temperatures up to 32°C (Fig. 3), supporting the idea that symbionts from this clade are opportunists with life history features that enable them to take advantage of ecological opportunity provided by the loss of other strains of zooxanthellae from the host following stress (Knowlton and Rohwer 2003).

Initial rates of infection were affected by temperature in two of the three symbionts (Fig. 2). In strain A6, the proportion of larvae infected decreased with temperature from 80% infection at 26°C to 10% at 34°C (Fig. 2). In strain C9b the proportion of larvae infected at 30°C was twice as high as at 26°C (Fig. 2). The proportion of larvae infected by strain C1 was uniformly low, perhaps as a result of the fact that this strain may not have a free living form and therefore be unsuitable for culture (see below).

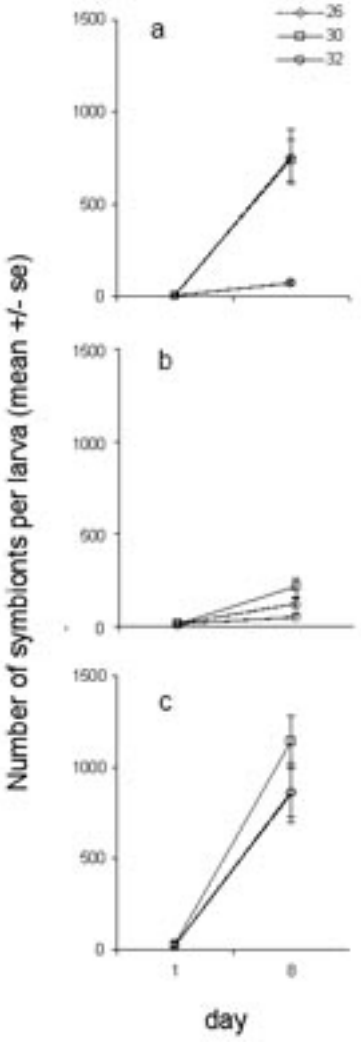

Figure 3. Change in the density of zooxanthellae strains (a = C3, b = C9b; c = A6) in *A. intermedia* larvae (n = 6).

Similarly, at 34°C the proportion of larvae infected was uniformly low (Fig. 2), suggesting none of the strains are capable of dealing with temperature 6°C above ambient. The different optimum temperature of infection in strains A6 (26°C) and C9b (30°C) suggests that certain strains may have a competitive advantage under different environments (Baird et al. 2007). However, within the range of temperatures examined these patterns of infection were not directly related to thermal tolerance of the zooxanthella strains.

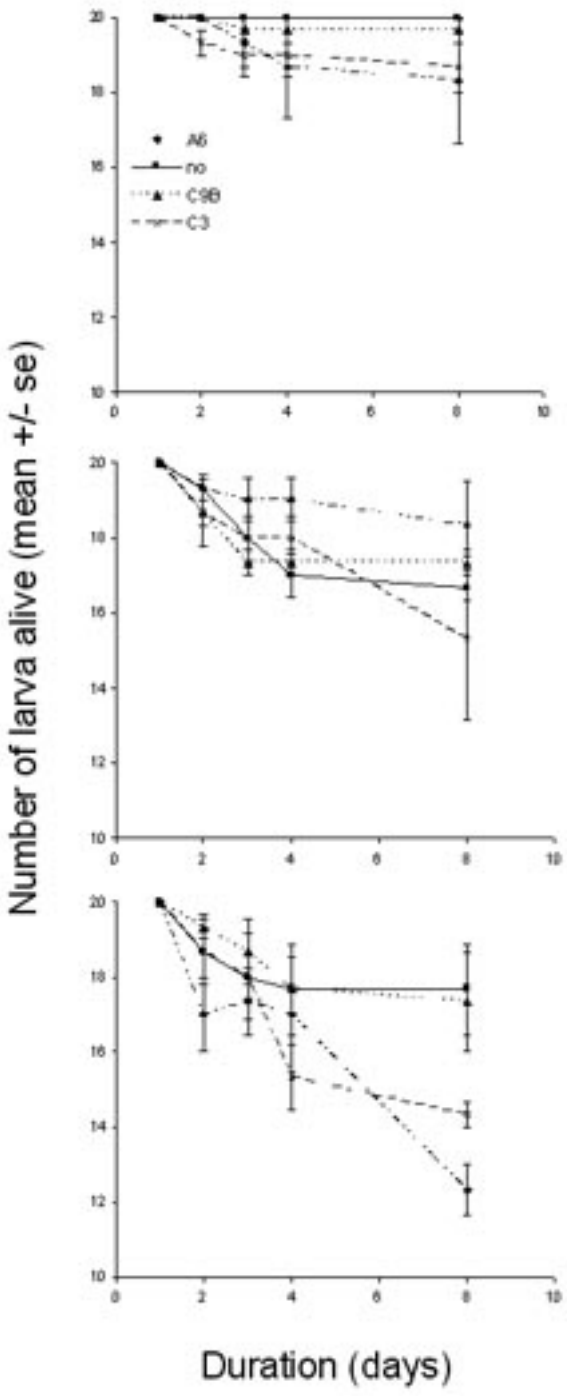

Figure 4. Survivorship of *A. intermedia* larvae infected with three strains of zooxanthellae plus non-zooxanthellate larvae at three temperatures (a = C3, b = C9b, c = A6; n = 6).

The growth rate of the zooxanthellae strains within larvae varied dramatically among strains and with temperature (Fig. 3). Strain C3 increased more quickly at higher temperature (i.e. 30 + 32 > 26) (Fig. 3). Strain C9b increase slowly at all temperatures with little difference in density among temperature treatments after 8 days (Fig. 4). Strain A6 increased rapidly at all temperatures (Fig. 3).

These data suggest there may be some trade-off in terms of thermal tolerance vs. growth rate, with strain C9b being the most thermally tolerant and also having the slowest rate of population increase in the host. Similar trade-offs between growth and tolerance have been suggested for clade D vs. clade C zooxanthellae in coral on the GBR (Berkelmans and van Oppen 2006).

There was little difference in the performance of the different holobionts at 26 or 30°C, however, at 32°C both A6 and C3 holobionts had lower survival (Fig. 4). This suggests that zooxanthellae may be an added burden to larvae when under stress (Yakovleva et al. 2009).

A number of methodological issues may have affected the results. More recent research indicates that the maximum rates of infection are not achieved until 5-7 d post spawning (Yasuda et al. 2007). Our infection experiments commenced 3 d following spawning. While a high proportion of larvae were infected in some groups, for example, 80% of larvae were infected by strain A6 at 26°C, the results may have been different if larvae were at a stage more susceptible for infection. Furthermore, the high temperature treatment was probably too extreme. Very few larvae were infected by any strains at 34°C which is nearly 6°C above ambient at this time of year in Okinawa. Future work should examine infection using more treatments over a narrower range to more completely describe the functional response of larval infection to temperature. Also, other differences between some of the zooxanthellar strains could potentially affect rates of infection. In particular, strain A6 is not an intra-cellular symbiont, rather it is found in the haemal sinuses of the clam mantle (Farmer et al. 2001). Also, strain C1, isolated from *Seriatopora caliendrum*, is transmitted vertically i.e. directly into the oocytes of offspring and therefore may not exist outside the host. In contrast, strains C3 and C9b are both inherited horizontally i.e. they must be acquired anew in each generation, and therefore must have a free living stage in their life history. Finally, to effectively explore the effect of functionally different strains on the host performance it would have been ideal to wait until zooxanthella densities had stabilized within the host. This may take 4-6 weeks in coral larvae (Baird et al. 2006) which have the potential to host 1000s, to tens of thousands of zooxanthellae per larvae (Edmunds et al. 2005).

Abstract. This study investigated the potential protective role of the host by exposing coral larvae infected with two distinct clades of *Symbiodinium* (A and D) in two conditions, cultured and *in hospite*, to three combinations of heat and light levels (control: 24 °C + 40 μmol photons m^{-2} s^{-1}; high temperature and low light (HT+LL): 31 °C + 40 μmol photons m^{-2} s^{-1}; high temperature and high light (HT+HL): 31 °C + 390 μmol photons m^{-2} s^{-1}). HT+HL treatments decreased maximum quantum yield of photosystem II, F_v/F_m, in both cultured and *in hospite* zooxanthellae, however, the effect was more pronounced in cultured samples. HT+LL led to a decrease in maximum relative photosynthetic electron transport rate ($rETR_{max}$) only in cultured algae, while high light reduced $rETR_{max}$ in both *Symbiodinium* growth conditions, with $rETR_{max}$ approaching zero in cultured *Symbiodinium*. When *Symbiodinium* cells *in hospite* were exposed to HT+HL treatments, non-photochemical quenching increased; however for cultured *Symbiodinium* it declined drastically indicating that this particular form of photoprotection was depleted. These results suggest that *in hospite Symbiodinium* sustain less photo-physiological damage from HT+HL treatments in comparison to their respective free-living counterparts suggesting that the coral host provides some degree of protection to *Symbiodinium* from thermal and light stresses.

Key words: Coral host, photo-physiology, stress, *Symbiodinium*.

Introduction

Symbiosis between corals and zooxanthellae (*Symbiodinium* spp.) is dependent upon the mutual exchange of nutrients, with the coral receiving photosynthetically fixed carbon (Muscatine 1990) in exchange for nitrogen and phosphorus from the host. The association is beneficial to the coral host because it gains an additional metabolic capability, which has been hypothesized as the reason why corals have been known to expand into a previously inhospitable environment, the oligotrophic waters of the world's tropical oceans (Douglas 1994). However, the endosymbiotic zooxanthellae may also have gained a similar benefit from their host. Shallow tropical waters are characterized as being a highly variable light and temperature habitat. The host could provide some photoprotection for the symbionts, whereas these conditions would be most challenging for the free-living equivalents of zooxanthellae. It is therefore possible that the host could provide photoprotection, as well as nutritional support for its symbiotic partner.

Non-photochemical quenching (NPQ) is a fluorometric response mostly driven by a decline in Fm' (light-adapted maximum fluorescence). The closure of PSII reaction centres is one cause of reduced *Fm'*. When a photosystem experiences high light, electron transport increases as does production of protons, leading to a pH gradient across the thylakoid membrane. This gradient in turn triggers the epoxidation of xanthophyll pigments to dissipate excess photon energy in the form of heat; this is known as NPQ.

Coral bleaching occurs when zooxanthellae are released or their pigments are degraded. This disassociation of the host and the algal symbiont has been linked in most cases to the thermally-induced dysfunction of the *Symbiodinium* photosynthetic machinery, in particular at the dark reactions (Jones et al. 1998) and/or PSII light reactions (Warner et al. 1996, Lesser & Farell 2004, Hill et al. 2004, Bhagooli & Hidaka 2006, Hill & Ralph 2006). Photosystem II (PSII) and the photosynthetic electron transport rate of *Symbiodinium* are, directly and/or indirectly via

dark reactions, altered under thermal and/or light stresses (Bhagooli & Yakovleva 2004). A range of genetically distinct clades of symbionts has been found in association with corals, clams and other reef invertebrates. Differential coral bleaching due to environmental stress in adult cnidarians harboring different clades of *Symbiodinium* has also been documented (Rowan 2004, Berkelmans & van Oppen 2006).

The present study used two strains of *Symbiodinium* that were infected into aposymbiotic larvae and exposed to thermal and/or light stresses to investigate the potential role of the coral larval host in protecting their symbionts' photo-physiology.

Material and Methods

Four colonies of the broadcast spawning coral *Favia pallida* were collected from the reef crest at Little Pioneer Bay on Orpheus Island (18°46'S, 146°15'E) in the Central Great Barrier Reef (GBR), Australia, on the night prior to spawning (19th November 2005) and transported into flow through aquaria at the Orpheus Island Research Station. After spawning, larvae were cultured following the methods of Babcock et al. (2003) and maintained in 1-L glass jars in 0.02 µm filtered seawater (FSW) at initial densities of approximately 500 larvae per litre under cool-white fluorescent light tubes at a an irradiance of 40-60 µmol photons m^{-2} s^{-1} with a 12:12 h light: dark photo-period at temperature between 25 – 26 °C. FSW was changed weekly.

One group of larvae was infected with cultured (f2 media) free-living zooxanthellae obtained from the Australian Commonwealth Scientific and Industrial Research Organization (CSIRO) laboratories. These zooxanthellae were originally isolated from the clam, *Hippopus hippopus*, and have recently been genotyped as clade A (K. Ulstrup pers comm.). The second clade of zooxanthellae was isolated from *Acropora millepora* colonies from Geoffrey Bay on Magnetic Island (19° 09'S, 146°51'E) in the Central GBR. This population contains almost exclusively clade D zooxanthellae (Little et al. 2004). Zooxanthellae were isolated from adult tissue using a Water-Pik® containing FSW. Coral blastate was first filtered through a 350 µm nylon mesh to remove the mucus, homogenized and then centrifuged at 2,000 g for 5 min. The resulting algal pellet was re-suspended in FSW and centrifuged and this process was repeated twice to remove all animal tissue. Finally, zooxanthellae were re-suspended and added to the larval cultures at very high densities (600-800 cells). Zooxanthellate isolates were introduced to larval cultures within 30 min of preparation.

Three larvae infected with either clade A or D *Symbiodinium*, were exposed to three treatments: 24°C under 40 µmol photons m^{-2} s^{-1} light level (control LT+LL), 31 °C and 40 µmol photons m^{-2} s^{-1} (HT+LL), and 31°C and 390 µmol photons m^{-2} s^{-1} (HT+HL) for 8 h. Single larva in a transparent tube (cc. 2 ml) filled with 2 ml FSW was exposed at each combination of temperature and light treatment. Photosynthetic parameters describing the condition of the *Symbiodinium* were assessed using a PAM. After each trial, the fluorometer was used to measure rapid light curves (RLCs) followed by a 10 min dark-adapted maximum quantum yield of PSII, (F_v/F_m) measurement at the end of the 8 h exposure period. To measure the photo-physiological responses of the *in hospite* symbionts using the Microscopy-PAM, the larvae were transferred to glass slides with cover slip gently placed on top of them.

Fluorescence measurements of single *Symbiodinium* cells were performed using the Microscopy-PAM (Walz, Effeltrich, Germany) (Ralph et al. 2005). Maximum and effective quantum yield of PSII were determined according to the following expressions $(F_m-F_o)/F_m = F_v/F_m$ and $(F_m'-F)/F_m'$ or Φ_{PSII} where F_m is the dark-adapted maximum fluorescence, F_o is dark-adapted minimum fluorescence and F_m' is the light-adapted maximum fluorescence and F is the fluorescence prior to a saturating pulse (Genty et al. 1989). Electron transport rate (ETR) and non-photochemical quenching (NPQ) were estimated from the RLCs. The relative electron transport rate (rETR) was calculated as rETR = Φ_{PSII} X PAR. The rETR measurements were obtained by applying a series of saturating pulses under increasing actinic irradiance (0, 15, 50, 90, 150, 200, 250, 300, 350 µmol photons m^{-2} s^{-1}) at 10 s intervals yielding a RLC. The non-photochemical quenching (NPQ) derived from the expression $(F_m-F_m')/F_m'$ was determined as the highest NPQ value on the RLC. A double exponential decay function (Platt et al. 1980) was used to fit curves to the RLCs and quantitatively compare descriptive parameters such as α (initial slope of the RLC before the onset of saturation), E_k (minimum saturating irradiance) and $rETR_{max}$ (maximum relative electron transport rate) (Ralph et al. 2002).

Platt et al. (1980) equation:

$$P = P_s(1-e^{-(\alpha Ed/Ps)})e^{-(\beta Ed/Ps)}$$

Where P_s is the maximum potential rETR, α is the initial slope of the RLC, E_d is the downwelling irradiance (400-700 nm) and β is the slope of the RLC beyond the onset of photoinhibition. In the absence of photoinhibition ($\beta = 0$), the function can be simplified as

$$P = P_m(1 - e^{-(\alpha Ed/Pm)})$$

Where P_m is the photosynthetic capacity at saturating irradiance.
$rETR_m$ and E_k were estimated by the following equations:

$$rETR_m = P_s[\alpha / (\alpha + \beta)]/[\beta / (\alpha + \beta)]^{\beta/\alpha}$$

and

$$E_k = rETR_m/\alpha$$

High temperature with either low or high light treatment data were normalized to control values (24 °C + 40 µmol photons m^{-2} s^{-1}) from respective treatments to allow reliable comparison to be made between *in hospite* and cultured *Symbiodinium*. A 3-way ANOVA was performed to analyse the interactions among clade, growth condition and light. Tukey pairwise comparison of means was used to determine significant differences between treatments, $P < 0.05$.

Results

Symbiodinium growth condition (culture vs *in hospite*) but not clade (A vs D) had a significant effect on all the chlorophyll *a* fluorescence parameters measured (Table 1). Light alone significantly affected F_v/F_m, $rETR_{max}$, NPQ and α. Significant interactions of clade and light were observed for F_v/F_m only. An interaction between growth condition and light was observed for $rETR_m$, NPQ and E_k.

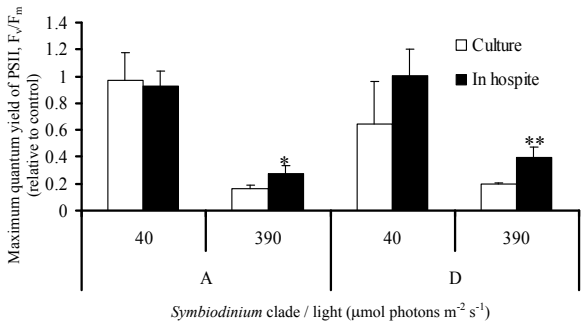

Figure 1: Chlorophyll fluorescence ratio, (F_v/F_m), of cultured (empty bars) and *in hospit*e (filled bars) clade A and clade D *Symbiodinium* exposed to low light (31°°C+ 40 µmol photons m^{-2} s^{-1}) and high light (31°C+390 µmol photons m^{-2} s^{-1}) for 8 h expressed as relative to their respective control (24°C + 40 µmol photons m^{-2} s^{-1}). Data represent means ± SD, n=3. Asterisks represent significant difference at $P < 0.05$, $P < 0.01$ and $P < 0.001$ for *, ** and ***, respectively.

High temperature plus high light treatments (HT + HL) significantly affected all chlorophyll fluorescence parameters measured in both exposure conditions except for E_k for *in hospite Symbiodinium* (Table 2). Under HT+HL conditions F_v/F_m (Fig. 1), $rETR_{max}$ (Fig. 2A) and α (Fig. 2B) declined significantly to less than 20, 9 and 25% of control values in culture and 40, 60 and 64% of control values for *in hospite Symbiodinium*, irrespective of clade.

Table 1. 3-way ANOVA analyses of (a) F_v/F_m and rapid light curve derived parameters (b) $rETR_{max}$, (c) relative NPQ, (d) relative α and (e) relative E_k. Clade = *Symbiodinium* A and D; growth condition (GC) = culture and *in hospite*; Light = 40 and 390 µmol photons m^{-2} s^{-1}. Asterisks represent significant difference $P < 0.05$.

Minimum saturating irradiance (E_k) in both *Symbiodinium* clades declined to less than 50% of control in culture condition only (Fig. 2C). NPQ for both *Symbiodinium* clades exhibited opposite trends (Fig. 2D). In culture, NPQ decreased to less than 20% of control, while for *in hospite* it increased by more than 2-fold relative to control values. High temperature and low light treatments did not significantly affect F_v/F_m (Fig. 1), α (Fig. 2B) and E_k (Fig. 2C) both in culture and *in hospite* states but significantly altered $rETR_{max}$ (Fig. 2A) and NPQ (Fig. 2D) in culture growth form only (Table 2). Exposure to HT+LL significantly decreased $rETR_{max}$ to less than 75% of control values but increased NPQ by more than 2-fold in culture and *in hospite* conditions in both *Symbiodinium* clades.

Table 2 Chlorophyll fluorescence parameters – F_v/F_m (dark-acclimated), ETR_{max}, α, E_k (from curve fitting of RLC), and NPQ (from RLC). Values are means ± SD. One factor analysis of variance and Tukey's pairwise comparison of means for $P < 0.05$; superscript letters represent similar means. Asterisks represent significant difference $P < 0.05$. For treatments see text.

Discussion

Here we show that the photo-physiology of zooxanthellae *in hospite* was better able to cope with heat and light stress than zooxanthellae of the same clade in culture suggesting that the coral host provides important protection to the photosynthetic apparatus of algae.

Maximum quantum yield of PSII (F_v/F_m) and rapid light curves derived parameters (α, $rETR_{max}$ and E_k) were affected by temperature and/or light stresses with *Symbiodinium* in culture being more sensitive than those *in hospite*, irrespective of clade. Maximum quantum yield of PSII (F_v/F_m) and efficiency of photosynthesis (α) both exhibited similar declines under thermal and light stresses (Fig. 2). A high temperature of 31 °C for 8 h when combined with low light did not affect F_v/F_m or α, however when combined with high light conditions did significantly reduce F_v/F_m and α of *Symbiodinium* in both culture and *in hospite* conditions, irrespective of clade. Iglesias-Prieto et al. (1992), also found temperatures above 30 °C impaired photosynthesis in cultured *Symbiodinium*, and Jones et al. (1998), Warner et al. (1996) and Hill & Ralph (2006) reported decreased F_v/F_m and α values in *in hospite Symbiodinium* when adult corals were exposed to 32 °°C under moderate (350 µmol photons m^{-2} s^{-1} or above) light levels, that is bleaching/stress conditions.

The capacity of photosynthesis ($rETR_{max}$) significantly decreased under HT+LL conditions only in cultured *Symbiodinium*, while HT+HL induced far greater photosynthetic impacts. $rETR_{max}$ of i*n hospite Symbiodinium* declined when exposed to HT+HL. Decreases in $rETR_m$ due to elevated temperature exposure are possibly related to reduced Rubisco activity (eg Lesser & Farell 2004). Another possible explanation for the latter results might be the relative light climate and optical filtering offered by the coral larval host.

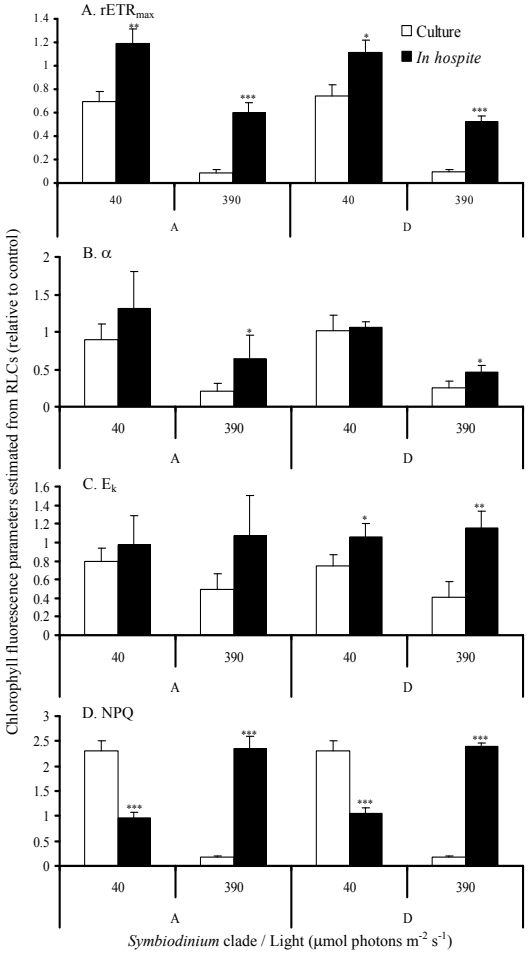

Figure 2: Derived chlorophyll fluorescence parameters ETR_{max} (A), α (B) and E_k (C) from curve fitting of RLC, and NPQ_m (D), the highest value from RLC, of cultured (empty bars) and *in hospit*e (filled bars) clade A and clade D *Symbiodinium* exposed to low light (31ºC+ 40 µmol photons m^{-2} s^{-1}) and high light (31ºC+390 µmol photons m^{-2} s^{-1}) for 8 h expressed as relative to their respective control (24ºC + 40 µmol photons m^{-2} s^{-1}). Data represent means ± SD, n=3. Asterisks represent significant difference at $P < 0.05$, $P < 0.01$ and $P < 0.001$ for *, ** and ***, respectively.

Symbiodinium cells *in hospite* were less affected than those cells maintained as free-living cultures, which tends to reflect different temperature stress thresholds for cultured (30 °C) (Iglesias-Prieto et al. 1992) and *in hospite* (32 °C) *Symbiodinium* of some corals. At HT+LL, $rETR_{max}$ decreased while NPQ increased, without any change in F_v/F_m, α and E_k, in cultured growth form only. This implies that the photosynthetic apparatus of cultured *Symbiodinium* under HT+LL was under significant stress. *In hospite Symbiodinium* did not exhibit any significant change in $rETR_m$ and NPQ under HT+LL conditions (Fig. 2). Under HT+HL conditions, the F_v/F_m, $rETR_{max}$, α, E_k

and NPQ decreased drastically in free-living *Symbiodinium*, indicating collapse of photosynthesis. *In hospite Symbiodinium* exhibited a significantly reduced decline in F_v/F_m, $rETR_{max}$ and α, increases in NPQ and no change in E_k suggesting reduced levels of photosynthetic stress. These findings are indicative of the potential role of the host as a buffer in protecting its photosynthetic symbionts. Whether it is just the optical filtering by the host or host related changes in pH, dissolved inorganic carbon (DIC) supply or access that provide photoprotection for the symbiont needs further investigation. Larvae usually possess photoprotective pigments called green fluorescent proteins (Bhagooli pers. obs.), as do adult corals (see review in Baird et al. 2009). Thus, it is reasonable to expect that the larval host can act as thermal and/or light protector to the algae under certain exposures, beyond which both the host and the algae would be stressed.

The findings that clade did not have an effect on the *Symbiodinium* responses to thermal and/or light stresses are not consistent with those of Rowan (2004) and Berkelmans & van Oppen (2006), which clearly showed that clade D *Symbiodinium* is more thermally tolerant than clade C. In the present study, clades A and D *Symbiodinium* responded similarly to thermal and/or light stresses. Rowan (2004) and Berkelmans & van Oppen (2006) found that a significant decline in F_v/F_m was observed after exposing adult corals harboring clade D to 32 °C for several days. Cultured and *in hospite* (within larvae) *Symbiodinium* cells showed a decrease in F_v/F_m after 8 h exposure at 31 °C and 390 µmol photons m^{-2} s^{-1} implying that clade D *Symbiodinium* is more thermally sensitive when held in cultured condition and when inside coral larvae compared to reported thermal responses of clade D in adult corals. It is noteworthy that Tchernov et al. (2004) has documented intra-cladal variation in F_v/F_m responses to thermal stress.

This study showed that *Symbiodinium* cells *in hospite* are more photosynthetically robust than when free-living and suggests a role of the host in protecting its symbionts and providing access to an environment that would otherwise be uninhabitable. Further studies are needed to explore light attenuation by host tissue in order to compare the amount of light that symbionts are exposed to when they are *in hospite* and in culture conditions. Moreover, investigations related to changes in pH, dissolved inorganic carbon supply or access to it might provide further mechanistic explanation for the host role in protecting its symbionts from environmental stresses.

Abstract Quantitative real-time PCR is a popular method for measuring gene expression in many biological organisms. The dinoflagellate *Symbiodinium* spp. lives in eukaryotic symbioses with reef-building corals and other marine invertebrates and protists. The use of quantitative real-time PCR to measure gene expression levels of the dinoflagellate symbiont has been limited by the lack of validated normalisation genes and the inability to purify mRNA from the alga without significant host contamination. Normalisation genes to correct for errors inherent to this technique are essential and as yet no validated normalisation genes have been identified for use in *Symbiodinium* gene expression studies. Three commonly used normalisation genes, β-actin, proliferating cell nuclear antigen (PCNA) and 18S rRNA, are tested for use as internal standards in light manipulation experiments of the major light harvesting protein complexes (chlorophyll *a* chlorophyll c_2 peridinin protein complexes - acpPC). Using the algorithm software program geNorm, β-actin and PCNA were found to be more stably expressed than the more highly expressed 18S rRNA genes, and result in similar gene expression profiles when used to normalise gene expression data for three different acpPC genes.

Key words: qRT-PCR, normalisation genes, *Symbiodinium* sp, light harvesting protein complexes

Introduction

The use of reverse transcription in conjunction with quantitative real-time polymerase chain reaction (qRT-PCR) is now a fundamental technique for measuring transcript levels of genes in a wide variety of organisms. The most commonly used approach involves the quantitation of transcript levels in relation to the level of an experimentally stable internal reference or normalisation gene. Alternatively absolute copy numbers of the transcript of interest can be calculated from a standard curve. qRT-PCR, while relatively straight forward to perform, has technical problems. These include RNA variability, variability in extraction protocols and different reverse transcription and PCR efficiencies (Bustin and Nolan 2004), while analysis of results is complicated by the method used for normalisation (Dheda et al. 2004). Appropriate selection of normalisation genes is important in controlling for these inherent problems, but the selection of an unstable gene may statistically influence results by either masking the detection of small changes or providing an incorrect result (Dheda et al. 2005). While growing numbers of studies test the potential of normalisation genes for use with organisms such as plants (Olbrich et al. 2008), Chromalveolata (Siaut et al. 2007) and Cnidarians (Rodriguez-Lanetty et al. 2008), the vast majority continue to use plasmid DNA or cell number (Demir et al. 2008) to quantify absolute transcript levels (Table 1). Use of qRT-PCR to measure gene expression where both partners are symbiotic eukaryotes is significantly more complicated than studies with single organisms or symbioses between eukaryote and prokaryote partners. The greatest challenge with symbioses between two eukaryote partners involves differentiating RNA contribution of the host organism from the symbiont and determining variability in the RNA contribution between samples.

In dinoflagellate symbioses studies qRT-PCR is primarily used to determine or compare the presence of different algal populations (example Loram et al. 2007) within scleractinian corals. In these studies use of normalisation genes or absolute transcript copy numbers is not necessary. Future approaches to eukaryotic symbioses studies are expected to incorporate exogenous RNA spikes. This enables quantification of symbiont contribution to RNA extracts, as was elegantly demonstrated for anthozoans harbouring endosymbiotic dinoflagellates (Mayfield et al. 2008). While utilisation of qRT-PCR to measure gene expression of coral or their single-celled phototrophic dinoflagellate of the genus *Symbiodinium* is still in the initial stages, it will become an important tool for elucidating the effects of increasing anthropogenic and environmental stresses on this important symbiotic relationship.

Here validation of three commonly used normalisation genes, 18S rRNA, β-actin and proliferating cell nuclear antigen (PCNA) are tested for stability under varying light conditions for future gene expression experiments with *Symbiodinium* sp. light harvesting chlorophyll *a* chlorophyll c_2 peridinin protein complex (acpPC) genes.

Table 1: Common normalisation methods used in plant, algae, symbiosis and bacteria.

Normalisation Standard	Organism
β-actin	Cnidaria (example Deboer et al. 2007) Dinoflagellate (Kobiyama et al. 2005) Plant (Jurca et al. 2008)
18S rRNA	Plant (Giorio et al. 2007)
GAPDH	Plant (Jurca et al. 2008)
Plasmid DNA or cell numbers	Dinoflagellates (example Demir et al. 2008) Raphidophytes (example Handy et al. 2008) Pelagophytes and haptophytes (John et al. 2007) Cyanobacteria (John et al. 2007)

Material and Methods

Symbiodinium *samples*

Coral branches from three colonies of *Acropora aspera* hosting *Symbiodinium* (clade C3) were collected from Heron Island (Great Barrier Reef (23°33'S, 151°54'E) in June 2005 and placed in four flow through aquaria. Light levels in two aquaria were reduced by shading (average daily light dosage 0.7 mol quanta m^{-2} d^{-1}), while the two remaining tanks were left exposed (average daily light dosage of 17.4 mol quanta m^{-2} d^{-1}). Over the course of the experiment the maximum irradiance recorded in the shaded tanks ranged between 27.3 and 98.9 µmol quanta m^{-2} s^{-1}, while the exposed tanks ranged from 573 to 1540 µmol quanta m^{-2} s^{-1}. One sample from each colony was collected from each tank at 1300 h on days 1, 3, 5, 7 and 9 of the experiment for RNA extraction.

RNA isolation

Symbiodinium were removed from the coral skeleton using an oral irrigator (WaterPik™) into 70 ml of 0.45 µm filtered sea water (FSW). The resulting homogenate was centrifuged for 2 min at 5000 g, the supernatant discarded and pellet resuspended and washed in 5 ml of FSW. This protocol was repeated a second time before the pellet was transferred to a clean tube and frozen in liquid nitrogen and stored at -80°C. Algal pellets were ground under liquid nitrogen and total RNA isolated using a RNeasy Plant Mini kit (Qiagen, Valencia USA). RNA was qualitatively assessed by a 0.9% formaldehyde agarose gel and quantified using a NanoDrop-1000 (NanoDrop Technologies, Wilmington USA).

qRT- PCR analysis

Reverse transcription and genomic DNA elimination was performed with QuantiTect Reverse Transcription kit (Qiagen, Valencia USA) in a 20 µl reaction using 500 ng of total RNA as template and a RT primer mix consisting of random primers and oligo-dT. Template dilution series were prepared to optimize quantification accuracy. After 4 fold dilution with ddH_2O, 3 µl of diluted template was analysed using the Rotor-Gene™ 6000 (Corbett Life Science, Australia). The PCR was performed with 7.5 µl of Platinium® SYBR® Green qPCR SuperMix-UDG (Invitrogen Corp, Carlsbad, USA) and gene specific primers (200 nM) for either β-actin, PCNA, 18S rRNA or one of three acpPC genes. The protocol was 95°C for 2 min, followed by 45 cycles of 15 s at 95°C and 30 s at 60°C with the temperature increasing 1°C every 5 s from 66°C to 95°C in a final melt stage. Each GeneDisc™-100 (Corbett Life Sciences, Australia) included reactions for one normalisation and one *Symbiodinium* acpPC gene, with samples run in triplicate and non-template controls in duplicate. Standard curves for each normalisation and *Symbiodinium* acpPC gene were generated on every run with five duplicates using a single template sample. An additional PCR efficiency check using four different RNA templates was conducted to ensure inter-disc comparability.

Primers for β-actin, PCNA and 18S rRNA were designed using combinations of MacVector Inc (USA) and DNASTAR Lasergene Primer Select (USA) based on alignments of multiple *Symbiodinium* cDNA sequences obtained from the NCBI GenBank database (www.ncbi.nlm.nih.gov) (Table 2). Alignments were constructed in BioEdit Sequence Alignment Editor (Hall 1999) using ClustalW Multiple Alignment (Thompson et al. 1994) and checked for specificity against nucleotide expressed sequence tags in NCBI GenBank database. Primer specificity was checked using coral cDNA extracted from *Acropora millepora* at both the prawn chip and donut developmental stages and *Symbiodinium* clade C3 cDNA extracted from *A. aspera*. *Symbiodinium* C3 acpPC primers were designed to an expressed sequence tag library (Leggat et al. 2007). acpPC primers were designed and checked as per normalisation genes (Table 2).

An additional primer check and negative control to determine the effect of coral contamination on *Symbiodinium* relative expression was performed. A total of 30 ng of template was used with decreasing amounts of *Symbiodinium* cDNA template (30 ng to 0 ng) mixed with increasing concentrations of coral cDNA from the donut developmental stage (0 ng to 30 ng of coral). qPCR was performed according to the above protocol using β-actin, PCNA, acpPCSym_1 and acpPCSym_10 primers and relative gene

expression determined using the $\triangle\triangle C_t$ method (Livak and Schmittgen 2001).

Statistical analysis

Results were analysed using the geNorm (http://medgen.ugent.be/~jvdesomp/genorm/) statistical algorithm software to calculate gene expression stability (*M*) for the three normalisation genes tested. The gene or genes with the lowest *M* value is considered the most stably expressed (Vandesompele et al. 2002). All target samples collected on Day 7, which were determined to be the most stably expressed, and normalised to the two highest ranking normalisation genes were subsequently analysed using geNorm to identify a calibration sample. The three *Symbiodinium* acpPC gene expression profiles were analysed in the relative expression software REST© (http://www.gene-quantification.de/rest-2005.html) (Pfaffl et al. 2002). PCR efficiencies were calculated for each standard curve generated and threshold fixed at 0.0859 for all C_t calculations. This threshold value represented the average detection threshold across the 15 runs with the upper and lower bounds used to scan for an optimal threshold set between 1 and a value necessary to exclude background noise. Melting curve analysis was performed for each assay to check reaction specificity.

Results

Primer specificity and coral contamination

Specificity of primer design for *Symbiodinium* sp. normalisation genes was examined using coral cDNA isolated and transcribed from prawn chip and donut developmental stages, both early post fertilisation aposymbiotic stages. qPCR primers designed for clade C3 *Symbiodinium* and amplified according to either standard PCR conditions or qPCR conditions outlined above, failed to amplify coral cDNA. Glyceraldehye-3-phosphate dehydrogenase (GAPDH) qRT-PCR primers designed for *A. millepora* were included as a positive control with pawn chip cDNA. When tested with C3 *Symbiodinium* cDNA, single amplicons of expected size were detected (data not shown).

A possible confounding factor in using qPCR to quantify symbiont gene expression is the unknown contribution of host RNA. To test for this the relative expression of acpPCSym_1 and acpPCSym_10 was examined with increasing concentrations of coral cDNA. The concentration of *Symbiodinium* RNA (which would probably include approximately 10-20% host contamination (Leggat et al. 2007)) used in the assay was decreased from 100% to 0.5%, while the coral cDNA was increased. The expression of acpPCSym_1 and acpPCSym_10 was then compared across this concentration range. A variation from a relative expression of 1, when compared to a sample with 100% *Symbiodinium* cDNA (30 ng) would indicate an effect of coral contamination. Only when *Symbiodinium* cDNA composed 0.5% (0.15 ng) of the total cDNA was there a significant deviation ($p = 0.02$) from a relative expression value of 1 (Fig. 1). No fluorescence was recorded in samples without *Symbiodinium* template (30 ng of coral cDNA only).

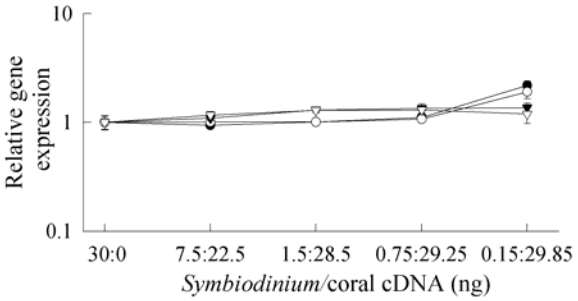

Figure 1: Effect of increasing the proportional coral cDNA concentration on relative expression of acpPCSym_1 normalised to β-actin (-●-) and PCNA (-o-) and acpPCSym_10 normalised to β-actin (-▼-) and PCNA (-▽-). Total template concentration is 30 ng for each sample and error bars indicating the standard error.

qRT-PCR efficiency

Amplification plots were analysed for the three normalisation and three *Symbiodinium* acpPC genes. Assay validations performed confirmed PCR efficiency and optimisation of procedure. Samples from Day 5 were removed from all expression profile analyses due to three samples being compromised prior to RNA extraction. Comparison of C_t values for each of the six genes on all sample days, including four additional templates run across multiple discs to ensure inter-disc comparability, confirmed minimal variation between PCR efficiencies, permitting comparison of genes and samples performed on different GeneDisc™-100 discs (data not shown).

C_t values for 18S rRNA were considerably lower than those of β-actin, PCNA and the three *Symbiodinium* acpPC genes across all sampling days (Fig. 2) indicating high transcript levels and the need for further optimisation of this gene.

Normalisation gene stability

β-actin (M = 0.467) was marginally more stable than PCNA (M = 0.498) with 18S rRNA the least stable (M = 0.687) under the specific experimental conditions used here. Target samples normalised to β-actin and PCNA from Day 7 of the experiment expressed the greatest stability. The most stably expressed target sample from Day 7 was used as the calibration sample and PCR efficiencies for each of the six genes from Day 7 were used to qualitatively compare the expression of the three acpPC genes subjected to varying light levels.

Relative gene expression levels for the three *Symbiodinium* light harvesting genes were calculated using the REST© method (Pfaffl et al. 2002) (Fig. 3). The profile of all three genes was similar when normalised to β-actin (Fig. 3a, c, e) with those samples shaded from light showing increased expression compared with light exposed samples. Light exposed samples exhibited minimal expression change across the nine day experiment and these results were replicated when acpPC genes were normalised to PCNA (Fig. 3b, d, f). acpPCSym_1 normalised to PCNA (Fig. 3f) were the only shaded samples not to increase expression.

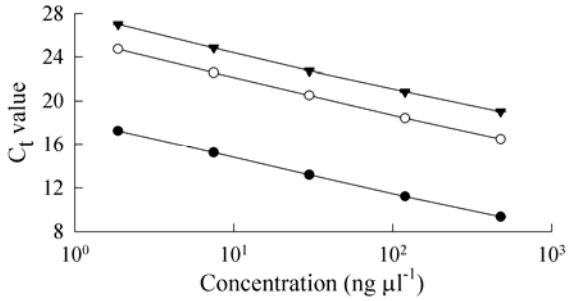

Figure 2: β-actin (-o-), PCNA (-▼-) and 18S rRNA (-●-) standard curves generated from amplification plots of serial four-fold dilution series. The plotted C_t is the average of triplicate samples and error bars (hidden by symbols) indicating the standard error.

Discussion

Three normalisation genes, β-actin, PCNA and 18S rRNA, were tested for stability in light manipulation experiments with *Symbiodinium* major light harvesting protein complexes (acpPC). Using the statistical algorithm software geNorm, β-actin was found to be marginally more stable than PCNA, and gene expression profiles for three acpPC genes normalised to β-actin and PCNA exhibited similar trends (Fig. 3).

PCNA was tested here rather than the more commonly used GAPDH to complement the use of β-actin and because synthesis of chloroplastic GAPDH is regulated over a diel cycle and exhibits greater than 50% identity in the region of overlap with the cytosolic isoform (Fagan et al. 1999). PCNA has been

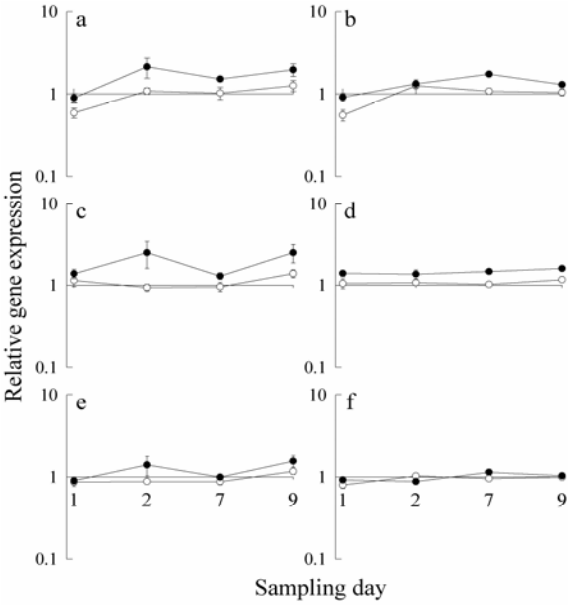

Figure 3: Expression profiles of *Symbiodinium* gene acpPCSym_10 (a, b), acpPCSym_9 (c, d) and acpPCSym_1 (e, f) normalised to β-actin (a, c, e) and PCNA (b, d, f) exposed to light (-o-) or shade from sunlight (-●-). Error bars represent the standard error for the averaged C_t values used to calculate relative expression for six biological replicates.

used as a normalisation gene in a range of animal species and humans (Schiller et al. 2003), is present in plant genomes (Suzuka et al. 1989) and has been isolated from a dinoflagellate where it was found not to significantly alter expression levels during cell cycle (Zhang et al. 2006), although this differs from other algal studies (example Wei et al. 2004).

Although using total RNA for normalisation is not always reflective of the mRNA fraction, it does enable the testing of 18S rRNA stability. In this study 18S rRNA was found to be unsuitable and would require additional optimisation. Compared with target mRNA transcripts the abundance of 18S rRNA is much higher (C_t value of approximately 10 compared to β-actin 17 and PCNA 19 indicating a 128-512 fold greater representation) (Fig. 2) and this causes difficulties when analysing data and determining the background baseline to subtract from the data (Vandesompele et al. 2002).

The overwhelming issue when using qRT-PCR with organisms such as *Symbiodinium* isolated from coral is whether varying RNA contamination influences the relative expression of the target genes. Results here suggest coral contamination is not a major factor and does not influence relative gene expression of *Symbiodinium* acpPC genes (Fig. 1) until transcript levels become very low, at which stage the variation between replicates increases. This suggests if valid normalisation genes can be identified for specific experimental conditions, the use of mixed

RNA populations will not confound results.

Microarray studies to date suggest dinoflagellate genes express small changes and that photosynthetic genes may only vary 2 – 3.4 fold (example Van Dolah et al. 2007). The identification of suitable normalisation genes is important if such minor changes in expression are to be detected and quantified. This study determined the stability of two normalisation genes and is an initial step towards validating a suite of genes with potential for use in *Symbiodinium*-coral gene expression work.

Abstract. Photosynthetic pigments of corals were analyzed by high-performance liquid chromatography (HPLC) to investigate the interrelationship between corals and their symbiotic algae, zooxanthellae (a dinoflagellate of the genus *Symbiodinium*). Coral samples were collected from Sesoko, Okinawa, Japan. HPLC analysis achieved the separation of more than 60 peaks of the pigments from more than 20 species of corals and 31 pigment types were identified. In addition to marker pigments of dinoflagellates, a variety of pigments including chlorophyll *b*,chlorophyll *d*, chlorophyll c_1, zeaxanthin, and lutein were detected. After brushing the surface of one of the common species of coral in the study area, *Montipora digitata*, to remove epizoic algae, the pigment composition of the coral was analyzed. However, the brushing treatment was not sufficient to remove most of the algae attached. These findings suggest that in addition to the pigments from symbiotic zooxanthellae, some of the pigments belong to epizoic and/or endolithic algae that grow in association with corals, such as cyanobacteria, green algae and diatoms. From these facts, corals are not only the host of symbiotic zooxanthellae, but also a community of diverse algae including cyanobacteria. This means that the coral host together with its associated algae may have an important role in terms of energy production for the whole reef ecosystem.

Keywords Photosynthetic pigments, HPLC, zooxanthellae, epizoic and endolithic algae, symbiosis

Introduction

The coloration of many reef-building corals is mainly derived from the photosynthetic pigments of their endosymbiotic, dinoflagellate algae of the genus *Symbiodinium*. The pigment composition of dinoflagellates is distinct from terrestrial plants and chlorophyte algae in containing chlorophylls c_1 and/or c_2, and the major xanthophylls peridinin or fucoxanthin (Kirk 1994). Dinoflagellates including *Symbiodinium* also contain the xanthophylls diadinoxanthin and diatoxanthin (Ambarsari *et al*. 1997), which are functionally equivalent to the photoprotective xanthophyll cycle pigments violaxanthin, antheraxanthin and zeaxanthin in terrestrial plants (Demmig-Adams & Adams 1996). *Symbiodinium* pigment profiles are dominated by chlorophyll *a* and peridinin, both of which comprise isomers in the HPLC eluant appearing as two or more peaks in HPLC chromatograms (Venn et al. 2006). All *Symbiodinium* also contain the pigments β-carotene and pheophytin *a* and additionally the minor xanthophyll dinoxanthin and the alteration product of diadinoxanthin, diadinochrome. These minor xanthophylls have been reported in HPLC studies of *Symbiodinium* (Kleppel et al. 1989; Ambarsari *et al*. 1997; Dove *et al*. 2006). Photosynthetic endolithic algae and cyanobacteria live within the skeletons of many reef-building corals. Under normal conditions, the green endolithic algae grow under less than 5% of the ambient photosynthetically active radiation (PAR) because of the absorbance of light by the zooxanthellae, coral tissues and the carbonate skeleton (Fine *et al*. 2005). However, there is little information concerning the diversity of such endolithic algae in corals.

In this study, we analyzed photosynthetic pigments of corals by HPLC to investigate the

interrelationship between the coral host and its epizoic and endolithic algae in order to understand their ecological role in the whole coral ecosystem.

Materials and Methods

Sampling of corals

Coral samples (see Table 1 for species list) were collected from Sesoko Island (26°38'54"N, 127°51'16"E) and Bisezaki (26°42'03"N, 127°52'35"E) located at the northern part of Okinawa, Japan. The collected corals were put into sterilized plastic bags, brought back immediately to the laboratory and stored at –30°C until treatment and pigment measurements.

Standard pigments

Chlorophyll *a*, pheophorbide *a*, α-carotene and β-carotene were purchased from Wako (Osaka, Japan). Chlorophyll c_2, chlorophyll c_3, divinyl chlorophyll *a*, alloxanthin, diadinoxanthin, fucoxanthin, 19'-butanoyloxyfucoxanthin, 19'-hexanoyloxyfucoxanthin, lutein, peridinin, prasinoxanthin, violaxanthin, and zeaxanthin were obtained from DHI Water and Environment (Copenhagen, Denmark). Chlorophylls *a* and *b* were extracted from spinach (*Spinacia oleracea*) leaves and purified by sugar-column chromatography according to the method of Perkins and Roberts (1962). Pheophytins *a* and *b* were prepared by acid treatment of the respective chlorophylls as described previously (Shioi *et al*., 1983). Chlorophyll *d* was isolated and identified from the cells of *Acaryochloris* sp. or thalli of the red alga, *Carpopeltis crispate*, collected from Itoh City, Shizuoka, Japan.

Treatment of Montipora digitata

For removing the epizoics, living coral tissue surfaces were brushed gently using a toothbrush. Alternatively, coral tissues were removed by water pik treatment and centrifuged at 5000 xg for 10 min to separate zooxanthellae from the coral tissues.

Extraction of pigments from coral species

Frozen corals from field sampling were crushed into small pieces and then homogenized with 20 mL of cold 95% (v/v) methanol in a mortar for pigment extraction. After extracting the pigments with sonic treatment for 5 min, extracts were then filtered through a syringe filter (0.2 μm, Millex-LG, Millipore) to remove cell and skeleton debris. To avoid the shape distortion of earlier eluting peaks, methanol extract (1.0 mL) was mixed with 0.2 mL of distilled water just prior to injection according to the protocol described by Zapata et al. (2000). These extracted samples (200 μl) were immediately injected into the HPLC. All samples were prepared under subdued light and subjected to HPLC analysis within 5 min after extraction to avoid pigment destruction.

HPLC analysis

HPLC analysis was performed according to the method reported by Zapata et al. (2000). The HPLC system employed was model LC-10A equipped with degasser and column oven, using a Waters Symmetry C_8 column (4.6 x 150 mm). All apparatus was Shimadzu (Kyoto, Japan). Pigments were eluted at a flow rate of 1.0 mL per min at 25°C with a programmed binary gradient elution system according to the method. Solvents used were, A: methanol:acetonitrile: 0.25 M aqueous pyridine solution (50:25:25, by volume), and B: methanol:acetonitrile:acetone (20:60:20, by volume).

Pigment identification and quantification

Separated pigments were detected spectrophotometrically with a photodiode array detector, Shimadzu SPD-M10A, with an optical resolution of 1.2 nm, measuring from 320 to 720 nm and monitoring 5 channels of representative wavelengths at 410, 430, 440, 450 nm, and 663 nm. The wavelengths used to indicate the pigments were 410 nm for pheophorbide/ pheophytin *a* derivatives; 430 nm and 663 nm for chlorophyll *a* species; 440 nm for neoxanthin and violaxanthin; and 450 nm for chlorophyll *b*, chlorophyll *c* species and other carotenoids. Each peak was identified by comparison with HPLC retention times and absorption spectra of the standards and the data from photodiode array detection. A coelution of the standard pigment with a sample was done to assay more precisely, if necessary. Concentrations of each pigment were calculated from the standard curves, which were created for those 20 pigments from the relationships of concentrations and peak areas of HPLC using the appropriate wavelengths described above.

Results and Discussion

Pigment analysis of various coral species

As shown in elution profiles of representative corals (Fig. 1), HPLC analysis achieved the separation of more than 60 peaks of the pigments from more than 20 species of corals. Among them, 31 pigment species were

identified. The results of pigment identification from 20 coral species are summarized in Table 1. The pigment species extracted from corals were different in each coral, despite the fact that the corals used in this study were collected from similar environmental conditions. In addition to marker pigments of dinoflagellates, a variety of pigments including chlorophyll *b*, chlorophyll c_1, chlorophyll *d*, zeaxanthin, and lutein were detected. Interestingly, chlorophyll *d*, which is only present in prokaryotic *Acaryochloris*, was found from several species of corals. The absorption spectrum of chlorophyll *d* is shown in Fig. 2.

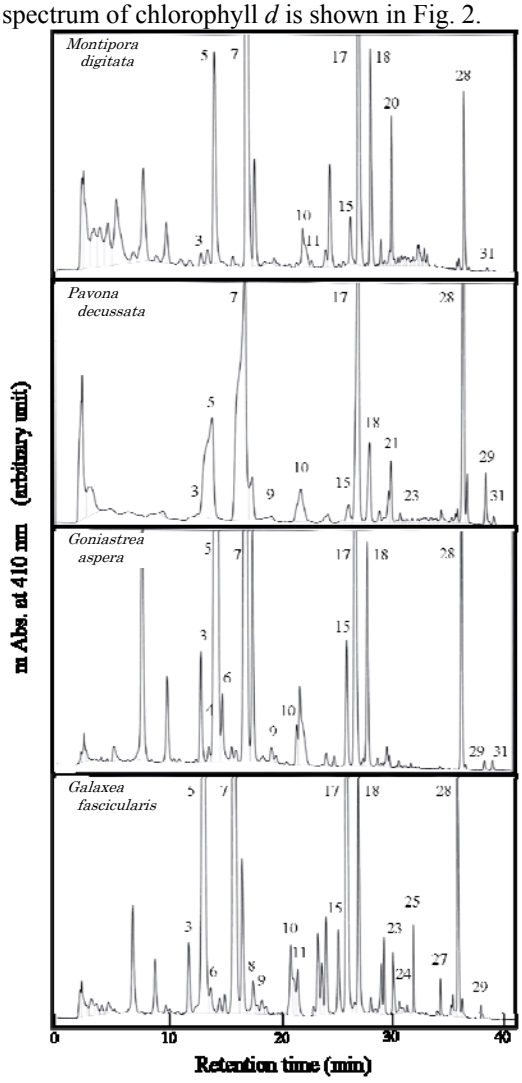

Fig. 1. Elution profiles of the photosynthetic pigments in representative coral species. HPLC conditions are described in the text. Peak numbers in elution profiles correspond to those in the identification table (Table 1).

Also, chlorophyll 684, which has a maximum absorption peak at 684 nm in the red band, was found in several species of corals. This is considered to be a degradation product of chlorophyll *a*. β-carotene is one of the marker pigments of dinoflagellates, but it was sometimes not detected. This is probably due to degradation of the pigment and it changing into its derivatives. As shown here, in addition to zooxanthellar pigments, various photosynthetic pigments from different algae were detected in corals. This finding shows that some of the pigments are probably due to the presence of epizoic and/or endolithic algae, growing on the coral surface or inside the coral skeleton, such as green algae, diatoms and cyanobacteria.

Pigment analysis of treated M. digitata

To examine whether algae are attached to the coral surface or not, brushing and water pik treatment of the coral were carried out. After brushing *M. digitata*, to remove epizoic algae, the pigment composition of corals was analyzed in the same manner. As shown in Table 2, even after brushing, similar types of photosynthetic pigments from different algae were detected in corals, in addition to zooxanthellar pigments, indicating that most of the epizoics could not be removed. Similar results were also obtained from water pik treatment. These facts show that epizoic algae are firmly attached and/or live inside the coral tissue.

Conclusion

In this study, we showed that some of the pigments detected by the HPLC technique in corals belong to various epizoic, endozoic and/or endolithic algae growing in association with the coral host. Moreover, these algae were unable to be removed by brushing treatment. Therefore, corals are not only hosts for their zooxanthellae, but also for various other algae. This means that the coral host and its algae might have an even more important role in the primary production of the whole ecosystem than otherwise suspected. Further research is necessary to investigate not only the relationship between corals and *Symbionidium*, but also interrelationships among coral hosts and their algal community.

Abstract. Light is often the most abundant resource within the nutrient poor waters surrounding coral reefs. Consequently, zooxanthellae (*Symbiodinium spp.*) must continually photoacclimate to optimise productivity and ensure coral success. To accurately assess *Symbiodinium* photoacclimation *in situ*, differences in acclimation strategies and bio-optical signatures need to be characterised between genetic types of *Symbiodinium.* Using a systematic series of laboratory experiments, eight types of *Symbiodinium* were cultured and examined using techniques such as active (FIRe) fluorescence, Photosystem I (PSI) and II counts and spectrophotometry. Two key 'strategies' of photoacclimation are known to exist amongst microalgae: a preferential modification of the light harvesting antennae (σ-based) or of the reaction centre bed (n-based) for PSII and/or PSI. Our measurements demonstrated that acclimation strategies employed by *Symbiodinium* were highly varied between algal type but despite this variability, many optical signatures were conserved. Acclimation strategies of intact *Acropora formosa* and *Seriatopora caliendrum* at two light levels were further examined using fluorescence and optical signatures to determine host contribution to acclimation. Overall, our results demonstrated that (1) biophysical (active fluorescence, photosystem-specific) but not bio-optical signatures were highly variable between algal types; consequently, bio-physical signatures that are altered by an adaptation of the algal community structure may be misinterpreted as photoacclimation and (2) host acclimation and modification of the light environment plays a key role in *Symbiodinium* photoacclimation.

Key words: *Symbiodinium,* chlorophyll *a* fluorescence, photoacclimation, absorption

Introduction

In the oligotrophic waters surrounding coral reefs, optimisation of photosynthesis is crucial for the success of the symbiotic partnership between the microalgae (*Symbiodinium spp*) and the host coral. This is achieved through the process of photoacclimation (phenotypic modification of the photosynthetic apparatus in response to changes in light availability). However, this phenomenon is not ubiquitous for all coral-*Symbiodinium* assemblages.

Multiple genetic types of *Symbiodinium* exist, and have been categorised into 8 major clades, A-H (Coffroth and Santos 2005). These clades can be further split into sub-clades according to the ribosomal Internal Transcribed Region 2 (ITS2) (LaJeunesse et al. 2001, Robison and Warner 2006). It was initially assumed that different clades conformed as 'eco-types' such as thermally tolerant or sensitive, but recent evidence has shown that variability exists within each clade (Iglesias-Prieto et al. 1994, 1997, Tchernov et al. 2004, Robison and Warner 2006, Hennige et al. 2009).

A coral species may comprise of a mixed community of *Symbiodinium* types, including different clades as well as subclades (LaJeunesse et al. 2004, Goulet 2006). The importance of this for coping with environmental change (including light) is debated (Baker 2001, Hoegh-Guldberg et al. 2002) but centres around whether corals can adaptively bleach (expel sub-optimal zooxanthellae and 'uptake' suitable types), or whether the *Symbiodinium* community already *within* the coral will 'shuffle' in dominance as conditions favour growth of one type over others. Regardless of potential benefits related to 'hosting' multiple *Symbiodinium* types, the presence of multiple types complicates interpretation of any *in hospite* photoacclimation study where the genetic identity of *Symbiodinium* is unknown, as genetic variability may 'mask' potential photoacclimation responses (Hennige et al. 2008, 2009).

Several photoacclimation strategies are known to exist for microalgae (Falkowski and Owens 1981, Suggett et al. 2007): cells can preferentially undergo changes to the light harvesting antennae

(photosynthetic unit, PSU, size) or of the reaction centre pool size (PSU number). This 'choice' varies, but recent work on phytoplankton has identified two strategies which conform to environmental conditions such as nutrient and light availability (Moore et al. 2006, Warner et al. 2006, Six et al. 2008). The two strategies involve either changes to PSU size or number and were termed σ versus n–type acclimation strategies respectively (Six et al. 2008). N-type acclimation tends to be found in generalist microalgae species which live in variable light environments and are not nutrient limited. Conversely, σ-type acclimation is better suited to uniform or low light environments (Six et al. 2008).

Methods for assessing photoacclimation are often destructive, so recent *in situ* coral photoacclimation studies have turned towards non-invasive techniques, such as chlorophyll *a* (chl *a*) fluorescence and optical reflectance. Chl *a* fluorescence can be used to infer photosynthetic efficiency and effective cross section-absorption (σ) of *in hospite Symbiodinium* (Gorbunov et al 2001). Consequently, studies have used chl *a* fluorescence to assess coral photoacclimation across environmental gradients (Ralph et al. 1999, Hennige et al. 2008). However, many studies, past and present, do not account for the community composition of *in hospite Symbiodinium*; consequently, studies often assess photoacclimation on the basis that the genotype of *Symbiodinium* does not change.

These coral-*Symbiodinium* assemblages are often considered as a single entity – the holobiont. Since some hosts only associate with certain *Symbiodinium* types, are some holobionts more suited to certain environments than others? To answer this, a better understanding is needed of the photobiological variability between different *Symbiodinium* types, and also how the host can play a role in modifying the internal light environment to optimise *Symbiodinium* productivity.

This study addressed 2 primary objectives: (1) to categorise variability between different *Symbiodinium* types using bio-optical and bio-physical techniques; and (2) to assess whether host acclimation and modification plays a role in *Symbiodinium* photoacclimation.

Material and Methods

Isolated Symbiodinium - Eight *Symbiodinium* types identified using the ribosomal ITS2 region; A1, A1.1, A2, A3, B1, B1*, B1** and F2 (Table 1) were cultured in 2L flasks at 26°C at two photon flux densities (PFD, 100 (LL) and 650 (HL) μmol photons m^{-2} s^{-1}) on a 14:10 light: dark cycle (see Hennige et al. 2009). Cultures were semi-continuous in artificial seawater media ASP-8A, (Provasoli et al. 1957) and were bubbled gently with air passed via a carbon column to keep pH constant (ca. 8.3). In exponential phase, aliquots of 500 ml were gravity filtered to concentrate material for subsequent measurements (Suggett et al. 2007). Triplicates were taken from sequential generations.

Table 1: *Symbiodinium* type according to ITS2 region, the host and region they were isolated from (adapted from Hennige et al. 2009)

Algal type	Host	Host origin
A1	*Cassiopeia xamachana*	Florida
A1.1	*Condylactis gigantea*	Jamaica
A2	*Montastrea spp.*	Florida
A3	*Tridacna maxima*	Palau
B1	*Aiptasia pallida*	Bermuda
B1*	*Aiptasia puchella*	Hawaii
B1**	*Acropora spp.*	Aquarium (UK)
F2	*Meandrina meandrites*	Jamaica

Corals – small fragments (ca. 6 cm) of *Seriatopora caliendrum* and *Acropora formosa* (from London Aquarium) were maintained in separate 250 ml water jacketed vessels under a light: dark cycle of 12: 12 at 26°C for 12 weeks. Media was circulated through the vessels at 40 ml $hour^{-1}$. Each vessel was integrated with an inflow, an outflow and an aerator to provide water exchange and circulation. A planktonic food supplement was added to the media reservoir to provide a constant external nitrogen source to all vessels. There were two light treatments; low light, ca. 40, and high light, ca. 170 μmols photons m^{-2} s^{-1}. These light levels represent reef depths in Indonesia of ca. 20 and 10 m respectively (June – September).

N versus σ strategies– Photosynthetic unit sizes, which are used to assess σ–type acclimation, were defined as the ratio of chl *a* to reaction centres in PSI (RCI) or RCII (Suggett et al. 2007, Hennige et al. 2009), and are considered to be indicative of the concentration of functional reaction centres (RCs). Cell counts were determined using a haemocytometer, and subsequently used to calculate n–type acclimation as mol RCII(I) $cell^{-1}$.

To assess chl *a* fluorescence of *Symbiodinium*, a Fluorescence Induction and Relaxation (FIRe) fluorometer (Satlantic), which generates single turnover (ST) and multiple turnover (MT) fluorescence transients was used (Fig. 1). A ST protocol is where the primary electron acceptor Q_A, is fully reduced through a simultaneous single turnover event of all PSII reaction centres (Suggett et al. 2008).

A U-3000 spectrophotometer with ϕ–60 integrating sphere (Hitachi) was used to determine sample optical density as outlined in Suggett et al. (2007) and Hennige et al. (2009).

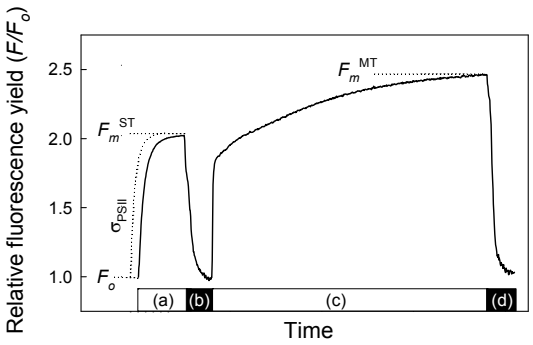

Figure 1: Example fluorescence induction trace using a FIRe fluorometer. Minimum fluorescence, F_o, maximum fluorescence (single turnover) F_m^{ST}, multiple turnover F_m^{MT}, and effective cross-section absorption of PSII (σ_{PSII}) are illustrated. Letters a - d refer to fluorescence induction stages along a time scale; a) describes the rise in fluorescence following a 100 µs single turnover (ST) event, b) is the 500 ms relaxation stage following the ST event, c) is the fluorescence rise from a multiple turnover (MT) flash over 600 ms and d) is the relaxation stage following the MT event over 1 s (adapted from Hennige et al. 2009)

To assess host and freshly isolated zooxanthellae absorption, coral tissue was removed from the coral skeletons using a waterpik. The slurry was separated into host and zooxanthellae portions by centrifuging twice at 1500***g*** for 15 min (Levy et al. 2003). The zooxanthellae pellet was re-suspended in a known quantity of seawater and the supernatant was regarded as the host fraction for subsequent spectrophotometry.

Surface area of the coral skeletons was quantified using tin foil and Image Tool analysis (UTHSCSA). Chlorophyll content of each sample and per colony was calculated using methanol and a spectrophotometer in accordance with Porra et al. (1989).

Results

Photophysiology - under steady state growth, significant variability was observed between algal types in F_v/F_m^{ST} ($F_{7,16} = 59.0$ and 35.8, $p < 0.001$ for LL and HL respectively) and σ_{PSII} ($F_{7,16} = 15.62$ and 3.81, $p < 0.05$ for LL and HL respectively), (see also Fig. 2). Mean values for F_v/F_m^{ST} and σ_{PSII} were ca. 25% and 5% lower under HL than LL respectively, but the magnitude of change was type-dependent.

Photosynthetic unit size and concentration- values of photosynthetic unit (PSU) 'size', chl *a*: RCII (I) used to assess σ–type acclimation, were highly variable with algal type (Data not shown). Most algal types exhibited a decrease in chl *a*: RCII between LL and HL but this was highly variable; algal type A1.1 exhibited an increase whilst type A2 exhibited no change in chl *a*: RCII (Table 3).

Changes to chl *a*: RCI between LL and HL were also highly variable between type, either increasing (A1.1), decreasing (B1, F2) or exhibiting little or no change (A1, A2, A3, B1*, B1**). Similarly, the cellular quotas (n-type acclimation) of both RCI and RCIIs were highly variable between algal types and upon an increase in growth PFD, most types decreased cellular RC content (Table 3). F2 was the only type to significantly increase cellular RC content from low to high growth PFD. Consequently, RC stoichiometry of PSII to PSI (RCII: RCI) did not vary in a consistent pattern for algal type or growth PFD.

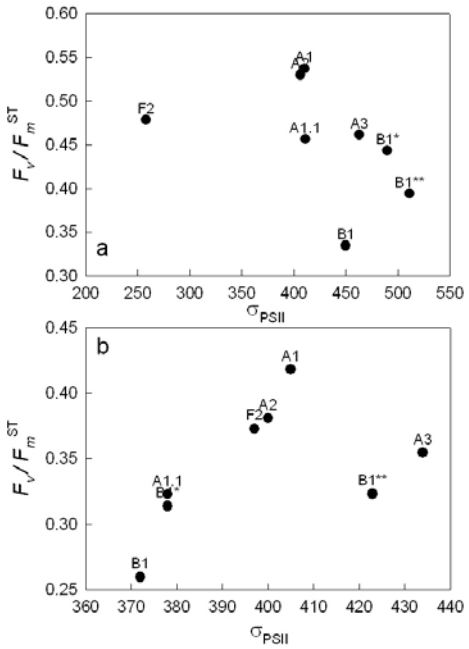

Figure 2: Maximum photochemical efficiency (F_v/F_m^{ST}) and effective cross section absorption of PSII (σ_{PSII}) of all *Symbiodinium* types under LL (a) and HL (b). For absolute values refer to Hennige et al. 2009

Table 3: Percentage difference in RC cell^{-1} (n) and chl *a* RC^{-1} (σ) for PSII and PSI between low and high light replicates. For absolute values refer to Hennige et al. 2009. Significant differences between LL and HL cultures are denoted with * (t-test, $p < 0.05$)

Algal Type	PSII		PSI	
	Number (RCII cell^{-1})	Size (chl *a* RCII^{-1})	Number (RCI cell^{-1})	Size (chl *a* RCI^{-1})
A1	-41.79	-17.46	-56.43*	10.27
A1.1	-72.62*	57.96*	-61.22*	11.55
A2	-57.08*	0.22	-46.69*	-36.24*
A3	14.93	-14.51	11.08	-3.68
B1	-73.90*	-44.53*	-78.96*	-31.18
B1*	-61.98*	-9.36	-46.41*	-35.70*
B1**	-6.9	-36.76	-51.9*	11.29
F2	34.95*	-57.07*	60.68*	-63.95*

Optical absorption, a^* (m^2 mg chl a^{-1}), was variable between algal type at LL and HL (Fig. 3), but was similar in shape for all algal types. Consequently, a^* was significantly correlated with pigment concentrations (Hennige et al. 2009). a^* at HL was

higher than at LL (Fig. 3) but percentage increase in absorption was type dependent.

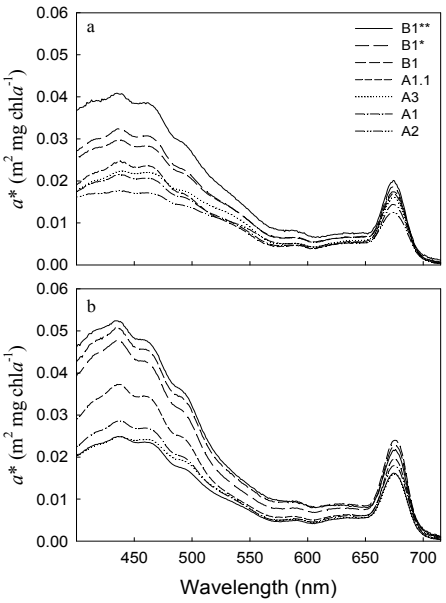

Figure 3: Optical absorption normalised to chlorophyll *a*, *a** (m^2 mg chl a^{-1}), from 400 to 715 nm for all *Symbiodinium* types except F2 under (a) LL and (b) HL.

Partitioning bio-optical signatures –freshly isolated zooxanthellae bulk absorption (Fig. 4a,c) was comparable to cultured *Symbiodinium* optical absorption (Fig. 3). Host tissue absorbed primarily at ca. 400 nm and decreased linearly to ca. 700 nm (Fig. 3a,b). Host absorption presented here was comparable to previous studies (Enriquez et al. 2005) but was higher in magnitude. Slurry absorption in Fig. 4a, was presented as the sum of both host and zooxanthellae fractions, which could differ by between ca. 2 – 10 % in magnitude of the measured slurry optical absorption.

When host fractions from *S. caliendrum* and *A. formosa* were compared between low light (LL) and high light (HL), HL corals had higher absorption. Additionally, *A. formosa* had an absorption peak (at both light levels) at ca. 500 nm (Fig. 4b) which was not present in *S. caliendrum* and represents the presence of a fluorescent protein, (confirmed with spectral fluorescence data (data not shown)). However, *S. caliendrum* host absorption was higher than *A. formosa* between 400 and ca. 460 nm.

Zooxanthellae bulk absorption (Fig. 4c) was influenced more by host species than light regime, since between LL and HL for each coral species, there was negligible change in zooxanthellae absorption (m^2 mg chl a^{-1}). Zooxanthellae isolated from *S. caliendrum* had higher absorption than *A. formosa* zooxanthellae (Fig. 4c).

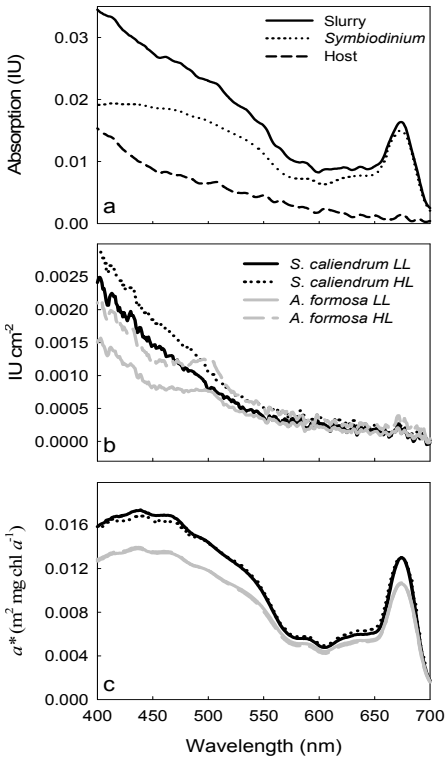

Figure 4: Example absorption characteristics (Instrument Units) of *S.caliendrum* tissue (slurry) and its constituents removed from the coral skeleton (a). Absorption of host tissue (IU cm^{-2}) from *S. caliendrum* and *A. formosa* from LL and HL conditions (b) and of isolated zooxanthellae (m^2 mg chl a^{-1} (c))

Discussion

Substantial variability was observed both in and between algal types in their n and σ-type photoacclimation strategies, consistent with previous studies (Iglesias-Prieto and Trench 1994, Hennige et al. 2009). The variability in bio-physical signatures such as F_v/F_m^{ST} was often larger between types than between environmental conditions. Consequently, if F_v/F_m^{ST} is used to assess photoacclimation across environmental gradients, *Symbiodinium* type must be accounted for to prevent an adaptation of the algal community being misidentified as photoacclimation.

Bio-optical signatures were conserved between types and varied according to pigment concentrations. Since *a** consists of photosystem II and I absorption,

$$a^*(\text{optical}) = a^*\,\text{PSII} + a^*\,\text{PSI} \qquad [1]$$

and optical absorption is controlled by both PSU size and number, we can consider *a**(optical) as

$$a^*(\text{optical}) = [\sigma \cdot n]\text{PSII} + [\sigma \cdot n]\text{PSI} \qquad [2]$$

Since *a** is conserved across *Symbiodinium* types, and n-type strategies are dominant across types, changes in σ between photosystems must therefore balance

changes in n. The predominant n-type strategy in *Symbiodinium* suggests the role of a generalist algal strategy when subject to varying light intensities, which are not nutrient limited (Six et al. 2008). Some types (A1.1, B1's and F2) also exhibited a σ-type strategy in addition to n (Table 3), which may confer additional benefits (Hennige et al. 2009).

Results here enabled direct comparison between zooxanthellae isolated from different coral hosts; the *internal* light environment for *S. caliendrum* was lower than that in *A. formosa.* Increased host absorption by *S. caliendrum* between 400 and 500 nm may have contributed to this. A lower light environment would promote the observed increase in algal absorption to optimise photosynthesis (Fig. 3c). These differences between host absorption could be attributed to increased host tissue volume per unit area as noted by Anthony et al. (2003), or by differences between host pigment content. The presence of a possible green fluorescent protein is noted at ca. 510 nm in *A. formosa* (Fig. 4b). However, skeletally enhanced light (not measured), may also have differed between host species and contributed to internal light variability (Enriquez et al. 2005).

In summary, both parts of the holobiont; the *Symbiodinium* and the host, are crucial to overall coral acclimation. However, the contribution of both fractions to acclimation is still not fully quantified. Importantly, bio-physical approaches need additional genetic identification (as opposed to bio-optical approaches) of the *Symbiodinium* to assess photoacclimation, consequently meaning that grouping algal clades as 'eco-types' may not be suitable. The host modification of internal light environment also differs between coral species, and in some cases may cause as much variability between species as between external light environments. Consequently, future photoacclimation studies will have to account for both *Symbiodinium* and host contribution to unravel coral photoacclimation.

Abstract. Ultraviolet radiation (UVR)-induced DNA damage and repair in freshly-collected *Aiptasia pallida* from Walsingham Pond, Bermuda were examined using the comet assay. In addition, animals were screened for the presence of mycosporine-like amino acids (MAAs). We found that field anemones produce relatively large quantities of four MAAs (mycosporine-2-glycine, mycosporine glycine, shinorine and Porphyra-334). Additionally, field anemones were capable of fully repairing DNA damage incurred during a 12-h exposure to UVR and PAR. It appears that *A. pallida* initiates nucleotide excision repair (NER) during the first 2 h of recovery in the dark. The majority of DNA strand breaks (SB) formed from NER are repaired within an 8-h recovery period. These results suggest that the ability of *A. pallida* to repair DNA damage and / or protect itself from the detrimental effects of UVR are important factors for its survival.

Keywords: Comet assay, DNA damage, *Aiptasia pallida*, Ultraviolet radiation.

Introduction

Tropical littoral zones experience some of the highest doses of ultraviolet radiation (UVR) on Earth (Frederick et al. 1989; McKenzie et al. 2003). Consequently, sedentary marine invertebrates in these habitats are exposed to biologically harmful levels of ultraviolet-A (UVA, 320-400nm) and ultraviolet-B (UVB, 280-320nm) (Shick and Dunlap 2002). Exposure to UVA and UVB can detrimentally affect survival, growth, and reproduction of shallow-water marine invertebrates from oxidative stress that results in structural damage to proteins and lipids and physiological impairment at the cellular level (Stochaj et al. 1994).

DNA damage is arguably the most harmful effect of UVR. Exposure to UVR generates the formation of cyclobutanepyrimidine dimers (CPDs) and 6-4 photoproducts (Ananthaswamy 1997).

DNA lesions are repaired via enzymatic mechanisms such as nucleotide excision repair (NER), base excision repair (BER) (Kantor 1995) and photolyase activity (photoreactivation).

In addition to UVR exposure, single strand breaks are caused during oxidative stress when reactive oxygen species attack the backbone of DNA. Double strand breaks, which are the most severe form of DNA damage, can occur if two single strand breaks are nearby one another (Kantor 1995).

Symbiotic marine cnidarians are especially susceptible to these stresses in that UVR often co-occurs with intracellular hyperoxic stress (due to photosynthesis by zooxanthellae) and elevated environmental temperatures. These factors contribute synergistically to create oxidative stress and have been linked to bleaching events (Lesser 1997).

Organisms employ behavioral and physiological adaptations to defend themselves against the harmful effects of solar radiation. The most commonly reported defense against UVR exposure is the production of mycosporine-like amino acids (MAAs).

While many studies show that organisms produce MAAs in response to UVR exposure, few have demonstrated a link between DNA damage and MAA concentration.

The use of the comet assay has been suggested as a sensitive and rapid technique for the detection of DNA strand breaks caused by genotoxins in the environment and has recently been adapted for use in studies with cnidarians (Michelmore and Hyatt 2004). Rinkevich et al. (2005) were the first to employ the comet assay specifically to investigate UVR exposure and DNA damage in corals (*Stylophora pistillata*).

Here we present evidence that field-collected specimens of *Aiptasia pallida* efficiently repair DNA damage incurred during a 12-h exposure to photosynthetically available radiation (PAR) and UVR.

Material and Methods

Collection of A. pallida

Specimens of *A. pallida* were collected at 15:00 hrs from Walsingham Pond, Bermuda and transported to the Bermuda Institute of Ocean Sciences (BIOS) on the 19th June 2007. Surface water temperature and salinity readings at the time of collection were 26 °C and 37 ppt, respectively. Upon return to the BIOS station the anemones were maintained on an indoor seawater table for no longer than 16 hrs before being exposed to PAR and UVR.

Experimental design

Field-collected anemones were randomly transferred into four 100 x 50 mm Pyrex crystallization dishes (n=5 per dish) and maintained in an outdoor seawater flow-through tank. In addition to the 4 UVR exposed dishes, a control group (n=3) was included which was not exposed to UVR. For the control, individual anemones were placed in a 30 ml beaker and nested into the crystallization dish. To block UV transmission the control dish was completely covered with 3 layers each of Mylar film (a UVB blocker) and C3a film (a UVA blocker).

Due to shading from mangrove trees at Walsingham Pond, light readings were lower than those at BIOS. At Walsingham Pond UVB measured 1.6 W m^{-2} and PAR 1104 µmol photons m^{-2} s^{-1}, whereas at the BIOS station unshaded UVB measured 2.51 W m^{-2} and PAR 1742 µmol photons m^{-2} s^{-1}. Therefore, animals were exposed to a reduced level of PAR and UVR to better represent the radiation found in their typical habitat of Walsingham Pond (Fig. 1).

In order to reduce PAR and UVR the holding tank which contained dishes of anemones was covered with a sheet of Solacryl® SUVT (Spartech Polycast) (which allowed UV and PAR transmission) and one layer of black fiberglass screen.

Anemones were subjected to 12 hrs of PAR and UVR (Fig. 1); receiving an approximate UVB dose of 24 kJ m^{-2}. Sunrise was at approximately 06:00 hrs and sunset not until 20:00 hrs. To cease exposure after 12 hrs, we covered the flow-through tank with 2 layers of neutral density filter to mimic sundown at 18:00 hrs. In this way, samples remained in the dark after PAR and UVR exposure for recovery periods of 0, 2, 4, 6, and 8 h. There were 4 replicate anemones for each recovery time. Animals were randomly chosen by removing 1 individual each from the 4 UV-exposed dishes. These individuals were processed immediately to determine the extent of DNA damage incurred via the comet assay. A control group (n=3) was also immediately processed after 12 h of PAR but in the absence of UVR.

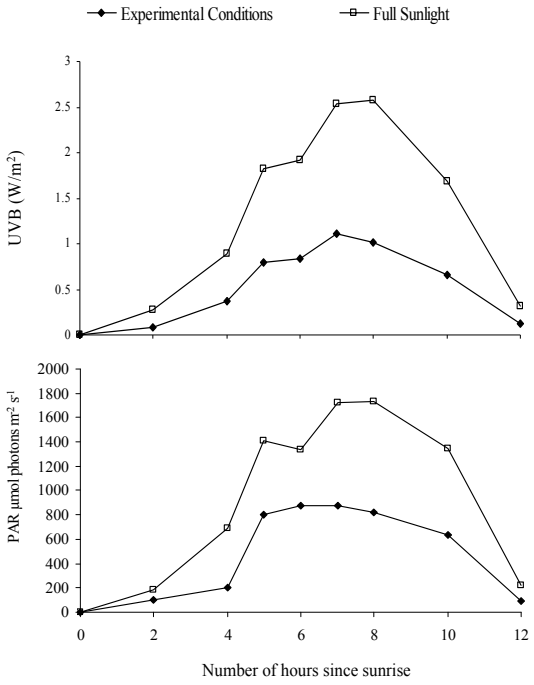

Figure 1: Light regime on 20 June 2007 at the BIOS. Field-collected symbiotic *A. pallida* were subjected to reduced PAR and UVR compared to full sunlight to mimic conditions observed at Walsingham Pond, Bermuda.

Assessing DNA damage using the comet assay

Host nuclei were isolated immediately following UVR exposures and subsequent recovery periods. This process occurred in a darkened room with no fluorescent lighting.

Anemones were carefully blotted with a Kimwipe to remove excess mucus then transferred to a Potter-Elvehjem homogenizer and homogenized in 1 ml of buffer (1x PBS + 0.25% sucrose; 100 µM EDTA (ethyl-enediaminetetra-acetic acid) pH 8; and 10% DMSO (dimethyl sulfoxide). Homogenization was achieved after 7 strokes of the Teflon pestle while rotating it 360° during each stroke.

The homogenate was passed through a cell strainer (50 µm) and carefully transferred using a Pasteur pipette onto a chilled 20% sucrose pillow to form a second layer. The cell suspension and pillow were centrifuged at 1340*g* for 2 min, which pelleted algal cells. The nuclei formed a surface layer on the pillow, which was transferred into a clean centrifuge tube and centrifuged at 4000*g* for 2 min to pellet the nuclei. The isolated nuclei were re-suspended in 0.7% low melting-point agarose.

Gel-bond™ slides were pre-coated with 150 µl 1% normal melting-point agar and covered with a glass cover-slip. Once the gels solidified the cover-slips were removed and 70 µl of nuclei suspension were layered onto the pre-coated Gel-bond™ slides, a new cover slip was added and the agarose containing

the nuclei allowed to solidify on ice in the dark for at least 15 min.

The cover-slips were removed and the slides transferred to a lysis solution (10% DMSO, 2.5 M NaCl, 100 mM EDTA, 10 mM Tris; pH 10) on ice and in the dark for 10 min. Following lysis the slides were immersed in alkaline unwinding buffer (300 mM NaOH, 1 mM EDTA; pH >10) on ice and in the dark for 5 min to unwind super-coiled DNA. Comet formation was achieved via electrophoresis in alkaline unwinding buffer at a constant amperage of 300 mA for 5 min.

Following electrophoresis, the slides were neutralized with three rinses in 0.4 M Tris; pH 7.5 for 10 min each, dehydrated with 95% ethanol for 5 min and allowed to air dry at room temperature for at least 24 h.

Dried gels were stained with 40 µl ethidium bromide solution (20 µg/ml)and examined under 400x magnification using a Zeiss Axioskopp epifluorescent microscope (excitation filter 510-560 nm green light, barrier filter 590 nm).

Digital images of the nuclei were taken with a Nikon, Coolpix 995 and analyzed using TriTek Comet Score™ (Freeware v.1.5). At least 50 nuclei per animal were analyzed for tail length (µm), and % DNA in tail and expressed as tail moment (i.e. the product of the two measurements). Results are expressed as means ± standard error of the mean (SEM).

MAA analysis

A sample of anemones (n=3) was immediately extracted for MAA content. Anemones were blotted dry and then homogenized in 1 ml 100 % methanol. A 100 µl sample was taken and diluted with deionized water for protein analysis (Bradford, 1976). The remainder was extracted for MAAs.

The homogenate was transferred into a microcentrifuge tube and extracted for 1 h in the dark at 4 ºC. Following centrifugation the supernatant was withdrawn and set aside. The pellet was extracted two more times. The pooled supernatant of individual anemones was passed through a SepPak C18 cartridge to remove pigment and lipid contaminants.

A spectrophotometric scan (280-400 nm) of the pooled extract (5x dilution) for each individual was performed on a Spectronic Genesys 5 UV-Vis to ascertain the presence of UV absorbing compounds. The pooled extracts were then evaporated to dryness using a Savant Speed-Vac SC100 and stored at -20 ºC until the samples were analyzed for MAA content via liquid chromatography followed by photodioarray and mass spectrometric analysis.

Statistical analysis

One-way ANOVA and post hoc multiple mean comparisons were performed on untransformed data for tail moment using SPSS v.15.0.

Results

MAA analysis

Spectrophotometric scans of methanolic extracts of field-collected anemones showed mean absorbance increased substantially in the range at which MAAs would be detected (302 nm – 360 nm) (Fig. 2). Chromatograms from methanolic extracts of anemones indicated the presence of UV-absorbing compounds (Fig. 3). Further investigation of extracts via photodiode array and mass spectrometry revealed measurable quantities of up to 4 MAAs: mycosporine-2-glycine; mycosporine-glycine which co-eluted with shinorine; Porphyra-334 and traces of 2 additional MAAs: usujirene / palythene and palythine.

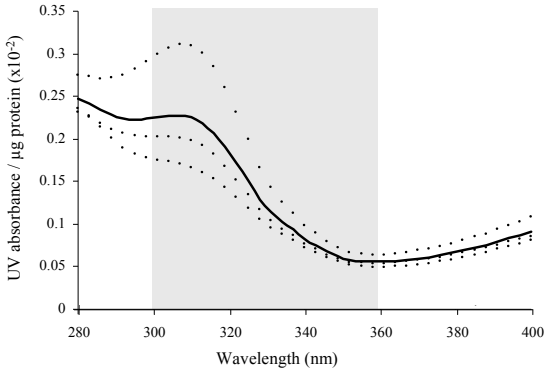

Figure 2: Spectrophotometric scan of 100% methanolic extracts from field-collected anemones. The shaded area represents the range at which MAAs absorb UVR. The solid black line represents the mean absorbance, dotted lines represent the scans of three individual anemones.

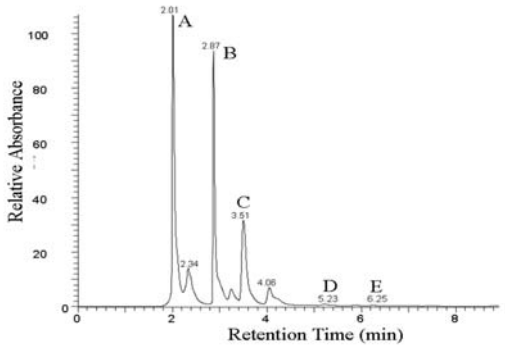

Figure 3: Chromatogram of methanolic extract from *A. pallida* Peak identifications: A - mycosporine-2-glycine; B_1 and B_2 - mycosporine-glycine which co-eluted with shinorine; C – Porphyra-334; D - usujirene / palythene and E – palythine.

Recovery Response

A one-way ANOVA indicated that DNA SB measured as tail moment varies significantly with recovery time ($p = 0.009$). Post Hoc multiple comparisons (Tukey HSD) revealed significant differences between repair times (Fig. 4).

While not statistically significant, tail moment increased by 127% in anemones which received 0 h recovery time compared to control organisms. This difference likely results from SB caused by a combination of UVR and oxidative stress, due to the fact that control groups did not have the added stress of UVR.

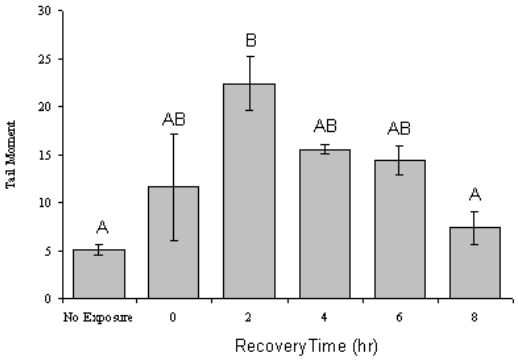

Figure 4: Genotoxic damage and DNA repair evaluated in isolated nuclei from field-collected *A. pallida* using the comet assay. The control group (n=3) received no UV exposure. Bars represent means ±SEM (n=4 anemones with 2 replicate gels per individual). Matching letters indicate non-significant differences at $\alpha = 0.05$

After a two-hour recovery period, tail moment doubled from that at the 0 h recovery time. This lag in time between UVR exposure and the subsequent increased number of breaks in the DNA indicates that excision of photoproducts is well underway at 2 h post-exposure.

The DNA SB at the 4 h recovery time dropped by 29%. However, the decrease in DNA SB from 2 h to 4 h is not statistically significant. This drop in DNA SB is likely attributed to the cells' gradual removal and repair of damage at specific sites of the DNA molecule.

There was not a further significant drop in DNA SB at the 6 h recovery time. However, after 8 h of recovery, tail moment was not significantly different from either controls or pre-exposure levels. This indicates that field-collected animals are capable of repairing DNA damage to a level equivalent to pre-exposure conditions within the course of a night.

Discussion

Spectrophotometric scans of extracts from field-collected anemones indicated peak absorbance at 310 nm, which implies the presence of relatively large quantities of mycosporine-glycine (λ_{max} = 310 nm). Further investigation of these compounds via LC/MS confirmed initial scans and identified measurable quantities of 2 MAAs: mycosporine-2-glycine and mycosporine-glycine, with smaller amounts of shinorine and Porphyra-334. Traces of usujirene / palythene and palythine were also found. Similar to our findings, Stochaj (1989) reported the presence of mycosporine-2-glycine, mycosporine-glycine and shinorine in *A. pallida* from Bermuda but did not find Porphyra-334. Banaszak et al. (1998) also reported the presence of only mycosporine-glycine and shinorine in *A. pallida* from Belize.

The production of MAAs as a defense mechanism against UV damage is well-studied in symbiotic marine cnidarians (Dunlap and Chalker 1986, Drollet et al. 1997, Banaszak et al. 1998). In a recent study, Torregiani and Lesser (2007) observed that corals taken from a depth of 1m had very low concentrations of MAAs and high CPD accumulation.

A defining factor for coral survival depends on the efficiency with which they repair DNA damage. Lesser and Farrell (2004) reported that host DNA damage in the coral *Montastraea faveolata* is intensified under high solar irradiance and thermal stress due to higher oxidative stress and CPD formation. Therefore, the ability to repair such damage is vital. Our investigation shows that field-collected *A. pallida* also exhibit an increase in DNA SB post-UVR exposure (Fig. 4). This is likely, in part, due to base and nucleotide excision repair. The literature regarding UV-induced DNA SB and repair in cnidarians is extremely limited; only one other study of this nature has been reported (Rinkevich et al. 2005). Similar to our investigation, Rinkevich et al. employed the comet assay to demonstrate an increase of DNA SB in a branching coral following a 1 h recovery period immediately after UVR exposure. This increase in DNA SB was attributed to BER and NER. However, a single repair time of 1 h is not sufficient to follow the time course of repair. The repair experiment in our investigation explores multiple recovery periods which allows for a better understanding of the course of DNA repair.

While future UVB levels are difficult to predict, current estimates suggest that it will take at least half a century before UVB levels return to pre-ozone depletion levels. Moreover, for the next century the ozone layer will be at its most vulnerable (Madronich et al. 1998). Our research offers a technique which is easily employed in field-collected samples and could be used to identify increasing DNA damage in stressed corals. This assay will better equip scientists trying to monitor the health of corals, predict bleaching events, or further study the effects of UVR exposure and elevated sea temperatures.

Abstract. Bleaching, the visible effect of the loss of zooxanthellae by corals has been observed in the last few decades with increasing frequency in most of the world's reefs. Since it usually leads to coral colony death and whole reef destruction, it has been the subject of several studies in recent years. In the present article we describe a method for causing complete, but reversible, bleaching in the common Red Sea coral, *Stylophora pistillata* by darkness stress. This treatment resulted in the reduction of the density of the zooxanthellae, the endosymbiotic algae living within the coral's cells. After 8 days in the dark the coral began to show visible bleaching, which a week later progressed to 70%, and by the 44th day we obtained complete bleaching. At that time no zooxanthellae or chlorophyll were detected in the coral tissue. Following the transferal of the corals to darkness, at first the algal cells exhibited a photoacclimative response, accumulating chlorophyll to levels above the initial values. Fragments that were 70% bleached showed full recovery 30 days after having been returned to light. In the course of recovery, cellular chlorophyll gradually decreased to control – and initial concentrations. From the recovery rate we calculated the maximal doubling rate in the log phase of zooxanthellae repopulating *S. pistillata* to be 2.5 days.

Key words: Coral, bleaching, recovery, chlorophyll.

Introduction

Coral reefs are built by hermatypic corals, in which there is a mutualistic symbiotic relationship between the coral host and single celled microalgae, the zooxanthellae, harbored within the endodermal cells of the coral. The coral affords protection to the algae and provides them with essential nutrients and CO_2 from its metabolic processes. In return, the algae supply the coral with high–energy photosynthate translocated to the animal host. On shallow, well illuminated reefs this nutritional source covers as much as 95% of all metabolic needs of the coral (Falkowski et al 1990). Under high light the energy suffices for maintenance, calcification, growth and reproduction whereas in deep lying, shaded reefs, supplementary predation on zooplankton is needed to satisfy these needs (Dubinsky et al. 1986).

The algae-coral association fine-tunes to ambient light and nutrient regimes by photoacclimation of the zooxanthellae and adjustment of their density, as well as changes in shape and orientation of the entire colony. The photoacclimation is evident from as much as 5 fold changes in the chlorophyll content of the symbionts (Falkowski & Dubinsky 1981; Dubinsky et al. 1984), whereas eutrophication brings about proliferation of the zooxanthellae and reduction of their contribution to the coral (Dubinsky et al. 1990). In branching species the response of the holobiont to high light results in profuse growth in all directions, whereas in the shade or dim light it fans out growing horizontally (Fricke and Schuhmacher 1983). The constant density of symbionts is kept in equilibrium with the growth rate of the colony, as the balance between their division rates, colony expansion and expulsion of excess cells is maintained. It has been found that hermatypic corals release about 0.1%-1% of the algal cells to the water every day, which is usually less then the 0.5%-10% of algae produced in the coral tissue during the same time (Stimson and Kinzie 1991; Hoegh-Guldberg 1994; Titlyanov 1996). In a few cases there are reports of digestion of some of the zooxanthellae by corals (Fabricius et al. 1996). These finely tuned equilibria are maintained on one hand by the translocation of most photoassimilated carbon to the host coral, and on the other hand by the paucity of the key nutrients, nitrogen and phosphorus needed for new zooxanthellar production. A typical doubling rate for the symbionts of *S. pistillata* in nature was 70 and 100 days for high and low light corals, respectively (Falkowski et al 1984).

This equilibrium can be upset if the coral is under stress; if the stress is strong enough the process of bleaching can be triggered, in which case the coral becomes colorless as the white color of the skeleton shows through the thin and transparent tissue (Hoegh-

Guldberg & Smith 1989). The loss of color can occur in two ways: **The coral losing its algae (bleaching);** it has been found that under heat stress the zooxanthellae are expelled from the coral tissue at rates about 1000 higher than in normal conditions (Hoegh-Guldberg & Smith 1989; Ruth et al. 1992). This phenomenon has been described by Glynn (1983) from direct microscopic observation. **The algal cells losing chlorophyll pigments (paling**) – when exposed to a combined heat and high light stress for 7 hours a reduction of ~x 7 in cellular chlorophyll levels has been measured (Salih et al.1998). Chlorophyll content per area of bleached *Agaricia tenuifolia* has been found to be 50 times less than normal (Lovelock et al. 1996).

The converse process, namely the out-of-control proliferation of the zooxanthellae, takes place whenever corals are exposed to anthropogenic (Dubinsky et al 1990) or rarely natural (Genin et al. 1995) eutrophication. This phenomenon, whereby zooxanthellar density increased fivefold in two weeks is detrimental to the colony, since under such conditions nutrients are used up by the algae in their multiplication severely curtailing the life-supporting translocation of photosynthate to the animal (Dubinsky and Jokiel 1994; Dubinsky and Berman-Frank 2001).

Bleaching events stop skeleton growth of the coral (Glynn 1983; Glynn and D'Croz 1990) and usually cause colony death and entire reef collapse (Brown & Suharsono 1990).

The chances of recovery following bleaching depend on the severity of the causative stress, its nature, intensity and duration, and on the conditions after the event. It has been suggested that in some cases it is possible that bleaching and subsequent recovery are the coral's way to achieve quick genetic change in the zooxanthellar community to populations better suited to withstand stress and react to environmental change (Buddemeier & Fautin 1993).

The recovery process can be achieved in two ways: fast reproduction of the "best" algal clone within the coral or by acquisition of a new clone from the water in the immediate environment (Goreau 1991; Rowan and Knowlton 1995).

Stylophora pistillata is the most abundant reef building coral in the Gulf of Eilat (Northern Red Sea) in both numbers and area coverage (Loya 1976). It is an "r" strategist (Loya 1972) which outcompetes all other species in the struggle to monopolize areas becoming available following natural or man-made disturbances. Since it also easily recovers from experimental handling and breakage into fragments it has been a favored model organism in the study of coral biology (e.g. Loya 2000).

Darkness Stress

Due to its dependence on the photosynthesis of the algal symbionts, darkness is a powerful stressor of zooxanthellate corals (Rogers 1979). By placing the coral in a light-tight container that blocks all light without affecting any other parameter such as temperature, pH or flow regime we easily cause darkness stress. Goreau (1959) found that when *Manicina areolata* was maintained in darkness for 10 days to two months it bleached.

Bleaching in darkness is caused by the loss of zooxanthellar cells, as found by Kevin & Hudson (1979) in a study of the cold water coral *Plesiastrea urvillei*.

Materials and Methods

Three colonies of *Stylophora pistillata* were collected from the reef near the Interuniversity Institute, Gulf of Eilat (Aqaba), Israel. Corals of 15-cm diameter were collected from artificial objects at a depth of 2.5-3.5 m. The corals were allowed to acclimate for one month in our main aquarium system under irradiance of 500 µmol quanta $m^{-2}s^{-1}$. Then the corals were divided into 3-cm-long fragments and glued with Super Glue Gel (Scotch, 3M) to plastic tips (Fig. 1).

Figure 1: *Stylophora pistillata* fragments during acclimation in our main aquarium system.

The fragments were left undisturbed for a period of 4 weeks for recovery and acclimation. Only fragments that showed a beginning of tissue growth (onto the plastic tip) were taken for the experiment.
The experiment was performed in a closed system at Bar-Ilan University.

Lighting was obtained from 3 fluorescent lamps of type T5 (10,000K, ATI), which delivered 500µmol quanta $m^{-2}s^{-1}$ at the water surface.

The Darkness Experiment

The experiment was conducted in two plastic containers, 10 L each, with openings for water exchange. The openings were connected by a "T" fitting preventing light from penetrating. A black plastic sheet assuring darkness covered one container and the other container was left uncovered as the control. The two containers were connected to the main water supply system. The light regime of the system was a 12 hours light and 12 hours dark photoperiod.

In each container were placed 30 fragments (a total of 60 fragments). Once every two weeks, 3 fragments from each container were removed and the following were performed: Determining algal areal density and measuring chlorophyll concentration per area and cell. Sixteen days after the beginning of the darkness treatment fragments showed 70% bleaching. At that time 9 fragments from the darkness treatment were transferred for recovery to the illuminated control tank. We monitored their recovery process over six weeks, by taking the same measurements described above for three fragments every two weeks.

We used standard methods for quantifying chlorophyll density in *Stylophora pistillata* and other coral species (Dubinsky et al. 1990; Titlyanov et al. 2000; Nordemar et al. 2003). The procedure requires sacrificing the sample using the Water-Pik method (Johannes and Wiebe 1970; Falkowski and Dubinsky 1981; Hoegh-Guldberg and Smith 1989; Edmunds and Gates 2002) to remove the live animal tissue with the zooxanthellae from the coral skeleton. The resulting homogenate was filtered through a 25-mm Ø glass fiber paper filter (Whatman GFC). The zooxanthellae collected on the filter were extracted in 10 ml of 90% acetone/water by grinding the filter with a glass/PTF homogenizer. The resulting slurry was filtered again through the same type of filter. Chlorophyll concentration was quantified by measuring the optical absorption at 665 nm and 755 nm with a Varian DMS 100 spectrophotometer according to the Jeffrey and Humphrey (1975) equations, and normalized to sample area.

The fragment area was determined using the standard aluminum foil weight method (Falkowski and Dubinsky 1981; Hoegh-Guldberg and Smith 1989; Edmunds and Gates 2002).

Results & Discussion

The difference between the control and the dark treatment was statistically significant, as already by the 7th day areal chlorophyll decreased by 70% (t-test, n=3, $p<0.05$). By the 44th day when the experiment was terminated, the dark treated fragments had totally bleached, and looked completely white; as the zooxanthellae were lost, the coral tissue became transparent and the white skeleton was revealed (Figure 2).

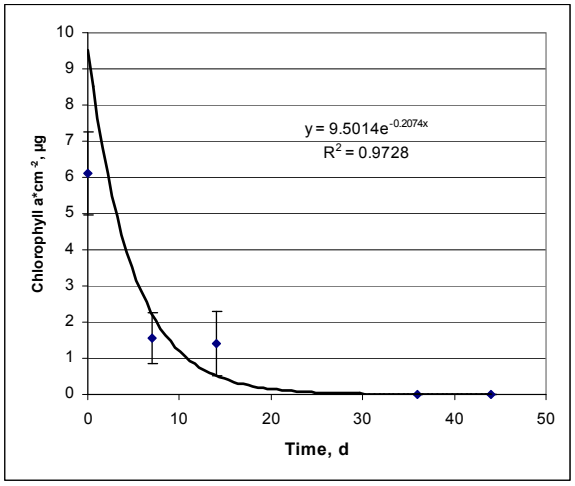

Figure 2: *Areal chlorophyll of bleached* S. pistillata *fragments in darkness (n=3).*

From the plot of chl *a* per zooxanthella cell (figure 3) we can learn that in the first 30 days the dominant factor in the bleaching in darkness was the loss of zooxanthellae, whose numbers began declining immediately; by the end of the experiment less than 1% of the symbionts remained.

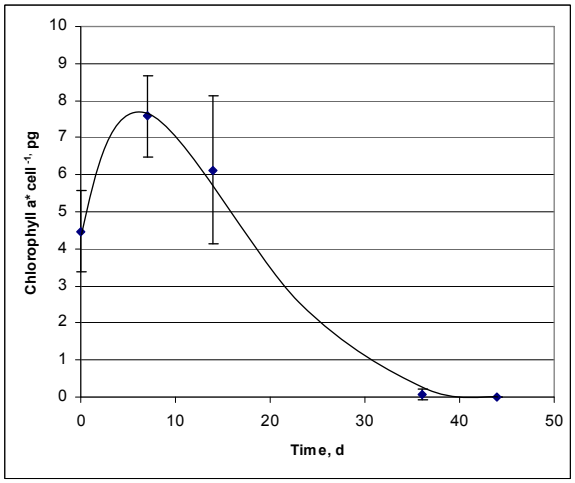

Figure 3: *Chlorophyll per zooxanthella cell of bleached* S. pistillata *fragments (n=3).*

The plot of chlorophyll *a* per zooxanthella (figure 3) shows that during the first 10 days after the corals were placed in full darkness the zooxanthellae were actually gaining chlorophyll, which is in agreement with the photoacclimation studies on *S. pistillata* (Falkowski & Dubinsky 1981; Dubinsky et al. 1983).

The recovery of the coral's chlorophyll concentration is shown in figure 4.

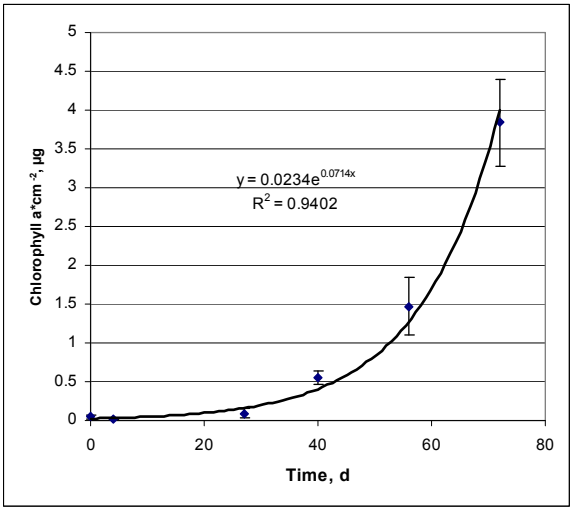

Figure 4: *Chlorophyll concentration in* S. pistillata *fragments recovering from darkness bleaching*

In the first 20 days the chlorophyll concentration in the coral tissue did not change much. In the plot following the changes in the chlorophyll in the zooxanthella cells (figure 5) we can see that in the first 10 days the chlorophyll content per cell was decreasing. We suggest that again it could be explained as a photoacclimation of the zooxanthellae upon being suddenly transferred from darkness to bright light.

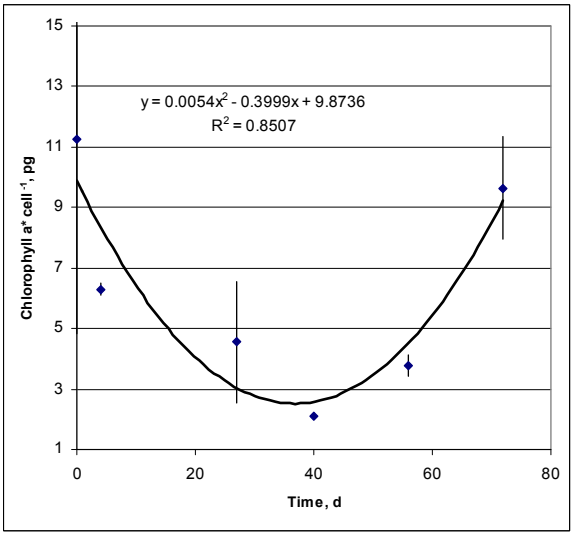

Figure 5: *Chlorophyll per zooxanthella in* S. pistillata *fragments recovering from darkness.*

After 20 days the chlorophyll and the algal population were being restored rapidly, until they reached initial and control levels at about the 70th day.

We followed the increase in zooxanthella density per cm^2 and calculated their rate of doubling and found that the fastest doubling time (after the initial lag period) was about 2.5 days (figure 6).

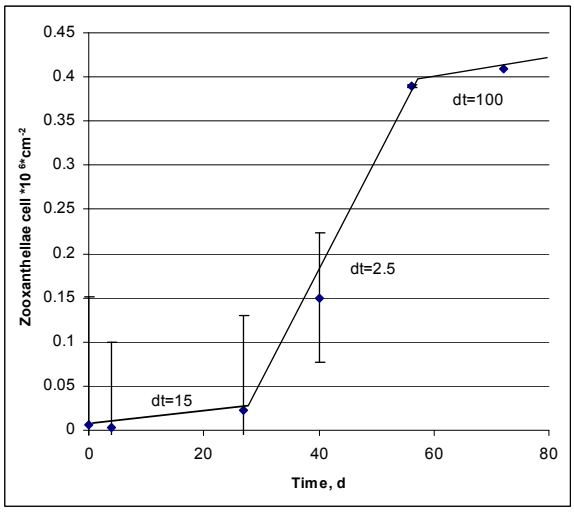

Figure 6: *Zooxanthella doubling rate in* S. pistillata *fragments recovering from darkness*

That is probably the maximal potential doubling rate of the zooxanthellae in the coral tissue when they are not constrained by their own population. Doubling times in steady state (presumably at their carrying capacity in the tissue) were determined as 70 and 100 days in high and low light *S. pistillata* colonies, respectively (Falkowski et al 1984).

Conclusions

The study showed that in the common Red Sea coral *S. pistillata* darkness leads to bleaching. However, presumably a few zooxanthella cells remained, and upon illumination, these rapidly repopulated the bleached coral tissue. It is especially noteworthy that the bleached corals survived in total darkness for nearly two months, and that the doubling rate of the zooxanthellae during the recovery phase was as short as 2.5 days, whereas in nature it was reported to be 70-100 days. We interpret it as representing a population's reaction to finding itself way below its carrying capacity, thereby realizing its maximal potential growth rate.

On the technical level the study illustrates the power of the described photographic method as a tool in coral research.

2) Department of Chemistry, Biology and Marine Science, University of the Ryukyus, Nishihara, Okinawa 903-0213, Japan

Abstract. We have established an experimental system to study the response of coral cells to stresses using coral cell aggregates (tissue balls). The objective of this study was to evaluate the use of tissue balls for studies of oxidative DNA damage in corals cells under thermal stress. Tissue balls prepared from dissociated cells of *Pavona divaricata* were exposed to high temperature (31°C) in the presence or absence of an antioxidant or to normal temperature (25°C). DNA damage of coral cells was investigated using a Comet Assay (alkaline single-cell gel electrophoresis). The comet tail length, which indicates the degree of DNA damage, was significantly longer in coral cells from tissue balls exposed to 31°C than those from the controls (25°C) or those treated at 31°C in the presence of an antioxidant, 10 mM mannitol. The present results suggest that coral cells suffer oxidative DNA damage under thermal stress. It was not clear whether DNA damage occurred in algal cells as algal DNA was retained within the cell wall and the comet tail was not observed. This study also showed that tissue balls provide us with a good experimental system to study the effect of stress and various chemical reagents on coral cells.

Key words: Coral, Comet assay, DNA damage, Bleaching

Introduction

Coral reefs are under threats due to increasing sea surface temperature (SST) that cause coral bleaching. A number of laboratory and field studies have reported the link between high temperature stress and coral bleaching (Hoegh-Guldberg and Smith 1989; Fitt et al 1993; Lesser 1997; Hoegh-Guldberg 1999). High temperature stress has been proposed to produce damage of the algal photosynthetic apparatus, which leads to production of reactive oxygen species (ROS) (eLesser 1997; Jones et al. 1998; Bhagooli and Hidaka 2004; Yakovleva and Hidaka 2004) Although cells have an enzymatic antioxidant system to scavenge the harmful ROS (Downs et al. 2002; Lesser and Farrell 2004), the excess ROS cause damage in cellular components such as protein carbonilation (Downs et al. 2002; Richier et al. 2005), lipid peroxidation (Richier et al. 2005) and DNA degradation (Lesser and Farrell 2004). Recent studies showed that apoptotic or necrotic death of host cells are involved in cnidarian bleaching (Lesser and Farrell 2004; Richier et al. 2006; Dunn et al. 2007). On the other hand, zooxanthellae expelled by coral hosts during bleaching exhibit cell degeneration and apoptotic or necrotic death (Franklin et al. 2004; Strychar et al. 2004). However, until now the direct information about the effect of thermal stress on the DNA level in reef-building corals is very limited.

We have established an experimental system to study the response of coral cells to stress treatment using coral cell aggregates (tissue balls) (Nesa and Hidaka, submitted). Dissociated coral cells aggregate to form spherical bodies, which rotate by ciliary movement. These spherical bodies (tissue balls) stop their rotation and become disintegrated when exposed to stress. The relationship between the survival time and zooxanthella density of tissue balls showed a negative correlation at 31°C, while no significant correlation between the survival time and zooxanthella density of tissue balls was found at 25°C (Nesa and Hidaka, 2009). The results support the hypothesis that zooxanthellae become a burden for host corals under thermal stress probably via production of harmful substances such as reactive oxygen species (ROS).

In this study the use of tissue balls for the study of oxidative DNA damage of coral and algal cells under thermal stress was evaluated. We used the comet assay (single cell gel electrophoresis) to detect DNA damage in individual target cells (e.g., Avishai et al. 2003; Rinkevich et al. 2005).

Material and Methods

Collection and Maintenance of coral specimens

Small colonies of *Pavona divaricata* were collected from the reef at Bise, northern Okinawa. Corals were then brought to the Nishihara campus of the University of the Ryukyus and were maintained in an aquarium provided with a subgravel filter at 26°C under 150 µmol quanta $m^{-2}s^{-1}$ on a 12:12h light/dark cycle for up to 2 weeks prior to use.

Preparation of tissue balls

Pavona divaricata fragments were rinsed gently with 0.22 µm filtered seawater (FSW) and then coral tissue was removed from the skeleton using a WaterPik (Teledyne, WP-70J). To remove the mucus produced during the isolation procedure, coral slurry was filtered through 180 µm nylon mesh. The slurry was then homogenized with a homogenizer and filtration through 40 µm nylon mesh was performed. The resulting homogenate was centrifuged at 1200 rpm for 5 min, and then at 1000 rpm for 5 min. The supernatant was discarded and the pellet was re-suspended in FSW using a vortexer. The suspension containing dissociated coral cells and zooxanthellae was incubated in a 24-well plate. In each well 1 ml of dissociated coral-zooxanthella cell suspension was incubated with 1 ml 0.22 µm FSW for one night at room temperature. After overnight incubation, dissociated coral cells and zooxanthellae became aggregated and achieved a spherical shape. These spherical bodies (tissue balls) started to rotate by ciliary movement. After one night tissue balls were transferred to a clean petridish with fresh FSW. Healthy (rotating) tissue balls of similar size were chosen under a stereomicroscope (Nikon-SMZ-10) and put separately in each well of a 96-well plate containing 280 µl FSW. These preparations were allowed to recover at room temperature for 3-6 hours before the stress experiments. Although tissue balls contained various numbers of zooxanthellae, the density of zooxanthellae in the tissue balls was not determined in this study.

Treatments of tissue balls

In the first series of experiments, tissue balls were exposed to normal (25°C) or high (31°C) temperature in filtered seawater (FSW) for 10 h. Two 96-well plates, each with 25 tissue balls, were prepared and one plate was placed in an incubator (Yamato, Program Incubator IQ820) set at 25°C and the other plate was placed in another incubator (Sanyo, MIR-152) set at 31°C. In both incubators, the plates were illuminated using a 19W fluorescent light and the light intensity measured by a light meter (LICOR, LI-250) was 35 µmol quanta m^{-2} s^{-1}. In the second series of experiments, tissue balls were exposed to normal (25°C) temperature in FSW or high (31°C) temperature in FSW containing 10 mM mannitol, a scavenger of hydroxyl radicals. In both series of experiments, the experiment was repeated 3 times.

The comet assay

To detect possible DNA damage in coral cells, we used a Comet Assay kit (Trevigen). In the comet assay, cells were embedded in agarose on a microscopic slide. Cells were lysed to remove cytoplasm and most nuclear protein, leaving supercoiled DNA as 'nucleoids'. During electrophoresis DNA is attracted to the anode, but if breaks are present, a "comet tail' of DNA extending from the nucleoid is seen. The size and shape of the comet reflects the extent of DNA damage.

After exposure to thermal stress, tissue balls were placed into 1 ml of ice cold 0.01M PBS containing 20 mM EDTA and dissociated into single cells by pipetting for two minutes. Cells were collected by centrifugation (1,500 g, 1 min) and re-suspended in 300 µl of 0.01 M PBS containing 20 mM EDTA. 50 µl of the cell suspension was mixed with 500 µl low melting agarose (LMA). 75 µl of this mixture was added onto a comet slide and homogeneously spread using a pipette tip. The slides were placed in a refrigerator (4°C) for 20 min. For coral cell lysis, slides were then immersed in a lysis solution containing 1% sodium lauryl sarcosinate (provided with the kit) for 30 min at 4°C. Slides were immersed in alkaline solution containing 200 mM EDTA (pH 13) at room temperature for 20 minutes. Slides were then placed on a horizontal electrophoresis apparatus. TBE electrophoresis buffer was added to the electrophoresis tray to cover the slides. Electrophoresis was conducted at 20-22 volts and 0.01 mA for 10 min at room temperature. After electrophoresis, slides were immersed in 70% EtOH for 5 min. DNA staining was performed by adding 50 µl SYBR Green I (SYBR Green I 10 µl + 1 X TE buffer 200µl) to each circle of slides. All steps were performed under dimmed light to prevent additional DNA damage during the procedure.

For zooxanthella cell lysis, we used a modified Comet Assay following Erbes et al. (1997). Slides were immersed in alkaline lysing solution containing ionic detergent (0.1% Sodium Dodecyl Sulfate) for 10 min at room temperature. Slides were immersed in alkaline electrophoresis solution for 5 min at 4°C. Slides were then placed on a horizontal electrophoresis apparatus. Alkaline electrophoresis solution was added to the electrophoresis tray to cover the slides. Electrophoresis was conducted at 20-22 volts and 0.01 mA for 10 min at 4°C. After

electrophoresis, slides were immersed in Tris buffer for 5 min.

Image analysis

Samples were visualized and photographed on a fluorescence microscope (Nikon OPTIPHOT-2) at 20 X or 40 X using a digital camera (Nikon Digital Sight DS-LI). Comet tail lengths were measured by using Image J (1.40) software. At least 50 comets were measured in each condition in each of three replicated experiments. Comet tail length is easy to measure and still is a good parameter of DNA damage in sample cells (reviewed by Lee and Steinert 2003).

Statistical analysis

The experiment was repeated three times and the average comet tail length in each condition was used as the statistical unit. A statistical program, Stat view for windows (5.0.1) was used for data analysis. A Mann Whitney U-test was performed to test the significant differences of the comet tail length among the treatment groups. A p value <0.05 was considered to be significant.

Results

DNA damage in coral cells

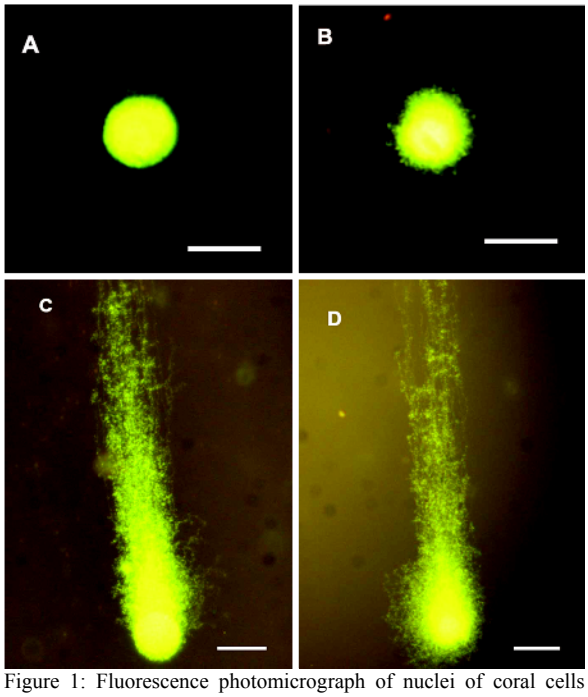

Figure 1: Fluorescence photomicrograph of nuclei of coral cells after alkaline single cell electrophoresis (Comet Assay). A and B, nuclei of coral cells from the control tissue balls kept at 25°C. C and D, nuclei of coral cells from tissue balls exposed to high temperature (31°C). Scale bar = 10 µm

The nuclei of coral cells from the control tissue balls (25°C) was circular without a tail (Fig. 1A) or with a very small tail (Fig. 1B), while the nuclei of cells from the tissue balls exposed to high temperature (31°C) showed comets with a long tail (Fig. 1C, D).

In this study, we measured comet tail length as an indicator of DNA damage of cells within the tissue balls exposed to different stress conditions. The comet tail length of high temperature-treated coral cells was significantly longer (Fig. 2) than that of the control cells (Mann Whitney U test, $p < 0.05$).

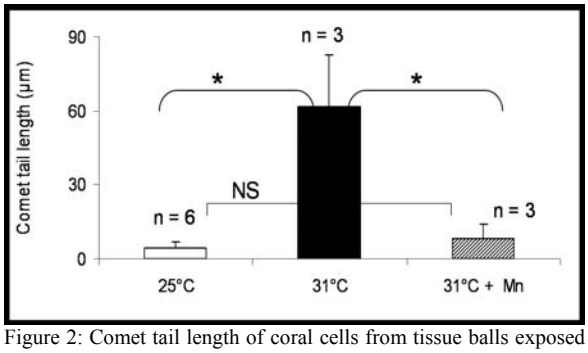

Figure 2: Comet tail length of coral cells from tissue balls exposed to different treatment conditions; open column represents the control (25°C), closed column represents high temperature (31°C) treatment and striped column represents high temperature (31°C) treatment in the presence of 10 mM mannitol.

The coral cells from tissue balls exposed to high temperature (31°C) in the presence of 10 mM mannitol showed significantly shorter comet tail length (Fig. 2) than those from tissue balls exposed to high temperature in the absence of mannitol (Mann Whitney U test, $p < 0.05$). There was no significant difference in the comet tail length between the cells from tissue balls exposed to high temperature in the presence of mannitol and those from the control tissue balls. The comet tail length was 4.3 ± 2.8 µm (n=6), 61.7 ± 21.2 µm (n=3), and 8.0 ± 6.0 µm (n=3) for the control, high temperature-treated tissue balls, and high temperature-treated tissue balls in the presence of the antioxidant, respectively.

DNA damage in algal cells:

The analyzed images of comet assays for zooxanthellae using alkaline lysing solution containing ionic detergent revealed that most of the zooxanthellae from both control and HT treatments showed a distinct head without a tail, or with a small tail (Fig. 3). The comet tail length of algal cells was 0.14 ± 0.19 µm (n=3) and 0.36 ± 0.18 µm (n=3), for the controls (25°C) and high temperature (31°C) treated tissue balls, respectively. No significant difference was found in the length of comet tails of zooxanthellae between the control and HT treatment (U-test, $p=0.275$).

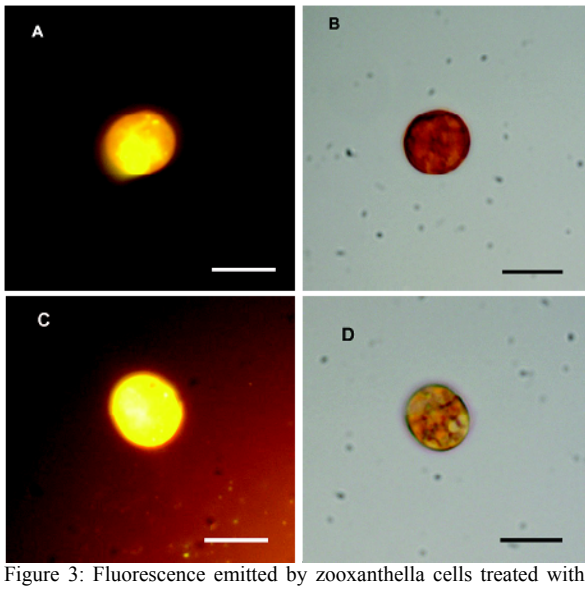

Figure 3: Fluorescence emitted by zooxanthella cells treated with different conditions (A, C); A and B represent control (25°C), and C and D represent high temperature (31°C) treatment. B and D are light microscopy images. Scale bar = 10 µm

Discussion

The present results clearly showed that coral cells suffer DNA damage under thermal stress. The addition of an antioxidant, mannitol, decreased the extent of DNA damage in tissue balls exposed to high temperature (31°C). This shows that tissue balls suffer oxidative DNA damage probably due to ROS produced by symbiotic algae under thermal stress. Addition of mannitol extended the survival time of *Pavona divaricata* tissue balls suggesting that this antioxidant is effective in protecting cellular integrity of corals (Nesa and Hidaka, 2009).

Apoptotic death of host cells (Richier et al. 2006; Dunn et al. 2007) or algal cells (Strychar et al. 2004) might be involved in cnidarian bleaching. While apoptosis results in DNA fragmentation, DNA damage may lead to apoptosis. Rinkevich et al. (2005) reported that UVB irradiation increases DNA breaks of coral and algal cells. It is likely that the DNA damage detected in the present study is due to direct action of ROS produced by symbiotic algae under thermal stress. Further study using inhibitors or inducers of apoptosis and other cell death pathways may be helpful to understand the death pathway of host and algal cells under thermal stress. The present results also suggest that tissue balls provide us with a useful experimental system for studies of cell death under stress conditions.

In the present study, nuclei of algal cells from tissue balls exposed to high temperature did not show a typical comet shape with a long tail. It is contrary to our expectations as symbiotic algae might be a source of ROS (Nesa and Hidaka, 2009). If ROS are produced in the chloroplast of the symbiotic algae, algal DNA is most likely to suffer oxidative damage. Rinkevich et al. (2005) detected DNA damage in isolated algal cells caused by UVB irradiation using the Comet Assay. It is not clear whether algal DNA did not suffer oxidative damage in our experiments, or DNA was actually fragmented but fragmented DNA was confined within a rigid cell wall. The modified Comet Assay, which uses an alkaline lysis solution, was applicable to the single-cell alga *Chlamydomonas*. But it is still to be confirmed whether the modified Comet Assay is applicable to *Symbiodinium* spp. Further studies using a transmission electron microscope might be helpful to understand the damage in algal cells under thermal stress.

Rinkevich et al. (2005) found that the holobiont (isolated coral cells containing symbiotic algae) is more sensitive to UVB radiation than isolated coral cells without symbionts or isolated algal cells. Their finding that symbiotic cnidarians are highly sensitive to ROS produced by UVB is consistent with other recent studies; tissue balls with higher densities of zooxanthellae had shorter survival times than those with lower densities of zooxanthellae under thermal stress (Nesa and Hidaka, 2009), and coral larvae with zooxanthellae had lower survivorship and higher levels of oxidative cellular damage than larvae of the same species that lack zooxanthellae (Yakovleva et al. 2009). Experimental systems using planula larvae, tissue balls, and isolated cells have their own advantages and disadvantages, but they might provide useful information on the role of symbionts in cellular damage of the holobiont under stress conditions.

5) Ghent University, Dept of Animal Production, Proefhoevestraat 10, 9090 Melle, Belgium

This study evaluates the capture efficiency of the scleractinian coral *Galaxea fascicularis* for four *Artemia*-based feeds: (1) live, non-enriched *Artemia* nauplii; (2) Instant Baby Brine Shrimp (IBBS, pasteurized *Artemia* nauplii); (3) live, SELCO-enriched *Artemia* nauplii, and (4) live *Artemia* nauplii enriched with SELCO that was supplemented with the antibiotics Sulfamethoxazole and Trimethoprim. All prey types were rapidly consumed by the corals (6-11 nauplii per polyp per hour), showing that (I), IBBS can be a cost-effective alternative to feeding freshly hatched nauplii, and (II), corals can be provided with specific additives via their food. The corals preferred live *Artemia* over IBBS, indicating that IBBS can be further optimised for use in coral reef aquaria. SELCO-enriched *Artemia* and medicated *Artemia* were also consumed at lower rates (40% and 30% lower, respectively) than non-enriched *Artemia*. However, these results are a useful first step towards (I), development of coral-specific feed-enrichments, and (II), oral treatment of diseased corals in captivity.

Key words: *Galaxea fascicularis*, feeding, *Artemia* nauplii

Introduction

The keeping of scleractinian (stony) corals in aquaria has become increasingly popular over the last few decades (Wabnitz et al. 2003). Numerous innovations in aquarium technology and improved methods for coral husbandry have made it relatively easy to keep captive corals alive (see overviews by Borneman 2001; Delbeek and Sprung 2005). The present study deals with two topics in coral husbandry that up till now have received relatively little attention: heterotrophic feeding and treatment of diseases.

Scleractinian corals are known to possess two major mechanisms for fulfilling their nutritional needs; photosynthesis through symbiotic zooxanthellae and heterotrophy. They ingest a wide variety of food, such as dissolved and particulate organic matter, sediment, bacteria and zooplankton (Sorokin 1973; Titlyanov and Titlyanova 2002). The importance of heterotrophy relative to autotrophy varies with species and habitat. According to Titlyanov and Titlyanova (2002), the relative contribution of photoassimilation to the total nutritional requirements of zooxanthellate corals ranges from 30 to 90%. Under high-light conditions, such as in shallow, tropical waters, the metabolic energy provided by photosynthesis alone exceeds the coral's daily energetic needs (Edmunds and Davies 1986 and references therein). Deep living corals, or corals living in turbid environments, are more dependent on heterotrophy (Falkowski et al. 1984; Anthony 2000).

Most aquarium corals thrive well in well-illuminated tanks. Therefore, much literature on culturing corals in aquaria focuses on technology for lighting, whereas quantitative studies on heterotrophic nutrition remain scarce. There is consensus among aquarists that at least a minimal amount of food is needed to supplement the resources provided by photosynthesis. Evidence is growing that enhanced feeding can stimulate coral growth considerably (Buongiorni et al. 2003; Ferrier-Pages et al. 2003; Houlbreque et al. 2004), thus emphasizing the importance of improving feeding methods for aquarium corals.

Artemia salina nauplii are widely used for feeding corals in aquaria and are commercially available in the form of dried cysts. Cysts hatch after 18-24 hours and the young nauplii can be fed immediately. Even though hatched nauplii can be

stored up to 48 hours (2-4 °C) without losing any nutritional value (Léger et al. 1983), methods to store them longer, in large quantities and especially without having to hatch them, could be more economically attractive in terms of labour and time management. For this reason, INVE® (Dendermonde, Belgium), a company specialized in food products for aquarium animals, has developed Instant Baby Brine Shrimp (IBBS): dead, pasteurized *Artemia* nauplii that can be stored for one year and fed until 6 weeks after opening. This product would be extremely useful for feeding corals in public and private aquaria. Therefore, the product was tested by comparing the rate at which the scleractinian coral *Galaxea fascicularis* captures IBBS to the rate at which it captures freshly hatched, live *Artemia* nauplii.

A second possibility to improve coral breeding and husbandry is provided by the technology to enrich *Artemia* nauplii with specific components. SELCO (Self Emulsified Lipid Concentrate) is one of the most commonly used enrichments in aquaculture. Specific components such as pro-biotics, antibiotics and food supplements can be coupled to SELCO so that they accumulate in the SELCO-fed nauplii. This technology has been successfully applied by Chair et al (1996) to treat diseases in aquacultured fish and shrimp by using *Artemia* nauplii as a vector for oral addition of antibiotics. This principle may also be applied to corals. During the last decades, extensive research has been done on coral diseases, as large outbreaks seem to become more common on reefs in the wild (Richardson 1998; Weil et al. 2006). Moreover, a disease outbreak can be disastrous in an aquarium. Recently, pathogens have been identified that cause, or are at least associated with coral diseases (Luna et al. 2007; Rosenberg et al. 2007). These findings will enable targeted treatment of coral diseases using specific antibiotics. In this study, a first step is made towards development of treatments of coral diseases through oral delivery of antibiotics: it was tested whether corals capture medicated *Artemia* nauplii. The uptake efficiency of eight colonies of *Galaxea fascicularis* was compared to their uptake efficiency for non-enriched nauplii.

Materials and Methods

Coral materials

Experiments were carried out in the laboratory of the aquarium in Burgers' Zoo, Arnhem, The Netherlands. The coral species used, *Galaxea fascicularis*, was grown in the coral nursery of Burgers' Zoo, registered under number ARKS 611377. One mother colony was fragmented into nine smaller colonies, which were attached to small PVC plates of 5 X 5 cm. Hence, all colonies were genetically identical. Eight colonies of 8 x 8 cm were used for the experiment. The number of polyps of each colony were counted as an estimate for coral biomass.

Methods

Feeding experiments were conducted in cylindrical Perspex incubation chambers with a volume of 1.4 l. The water used was taken directly from the tank in which the corals were kept in between experiments, to reduce ambient stress for the corals as much as possible. During experiments, conditions in the incubation chambers were kept the same as in the tank (Table 1). Water temperature was controlled by a TECO TC20 water cooler (TECO, Ravenna, Italy) and kept constant at 26°C. Light was provided by a 70 Watt HQI lamp, type BLV, 10.000 Kelvin. Water flow was controlled by an IKA® Big-Squid Ocean magnetic stirring plate and kept constant at 2.4 notches; at this speed (resulting in a water velocity of approximately 10 cm/s), the *Artemia* nauplii remained in suspension. Colonies were incubated one at a time for measurements of capture rates.

Table 1: Water conditions in the maintenance tank and in the incubation chamber.

Temperature	26°C
Salinity	34 ppt
Calcium	400-410 mg/l
Alkalinity	2.5-3.0 mEq/l
Nitrate	< 0.02 mg NO_3-N/l
Phosphate	< 0.01 mg PO_4/l

All feeding experiments were carried out by adding an initial concentration of approximately 2000 nauplii / l. Colonies were allowed to feed for 15 minutes. A pilot study had revealed that at these experimental settings, neither saturation of the corals, nor depletion of the food resource occurred, thus making it possible to compare capture rates for different feeds.

Before the start of each experiment, the concentration of nauplii in a concentrated batch was calculated by counting the number of nauplii in 15 replicate samples of 200 µl taken from that batch. From this, the volume to be added to the incubation chamber was calculated and added. Coral colonies were allowed to acclimatise in the respiration chamber for 20 minutes before introduction of the food. A sample of 50 ml was taken from the

respiration chamber with a syringe two minutes after adding the nauplii and the number of nauplii in the sample was counted under a binocular microscope. A second sample was taken 15 minutes after adding the nauplii. Capture rates were expressed as the number of nauplii cleared from the water in the respiration chamber in this 13 minute interval per coral polyp.

Experiments
All colonies were subjected to four feeding treatments:
Treatment 1: Non-enriched nauplii. *Artemia* nauplii from Great Salt Lake (Aquafeed, Utah, USA) were hatched by the Zoo's aquarists at temperatures of 25-26°C and used when 26 hours old.
Treatment 2: Ocean Nutrition Instant Baby Brine Shrimp (IBBS, dead *Artemia* nauplii, manufactured and supplied by INVE® (Dendermonde, Belgium).
Treatment 3: Enriched nauplii. 0.17 ml Easy DHA SELCO enrichment per litre was added once to 30 hour old *Artemia* nauplii. 19 hours after this, the batch was put on air and stored in a refrigerator during the day to ensure that the *Artemia* used at the end of the day had the same SELCO content as the ones used at the start of the day (Léger et al. 1983).
Treatment 4: *Artemia* were enriched with medicated Easy DHA SELCO, consisting of an emulsion with 5% Sulfamethoxazole/Trimethoprim (5:1), prepared by INVE®. Storage was done as described in Treatment 3.
Every treatment was repeated 3 times for each replicate colony (i.e. 24 experiments per treatment) before switching to the next treatment. The colonies were not fed by the aquarium staff on the days of the experiments. All colonies were given at least one day to recuperate from the experimental treatment in the maintenance tank, during which they were fed by the aquarium staff.

Blank controls
For every treatment, 8 blank control tests were conducted to check for the accuracy of the start concentration of added nauplii and for possible effects of the chamber on nauplii concentration. Blank tests were conducted following the protocol of the incubations with corals. A limestone coral skeleton in the shape of those of the experimental colonies was placed in the chamber to create a similar flow pattern.

Carbon content
The carbon content of the live *Artemia*-based products was measured to enable expression of uptake rate in organic carbon equivalents. Enriched *Artemia* are fed as nauplii of the Instar II type, while freshly hatched *Artemia* are fed as the smaller-sized Instar I type. Organic carbon was determined by the Wet Oxidation Method, using an OIC 700 Total Organic Carbon analyzer.

Data analysis
Statistical analysis of the data was done with SPSS 12.01. Data were tested for normality using the Kolmogorov-Smirnov and Shapiro-Wilk tests. Homogeneity of variances was tested by a Levene's Test for Equal Variances. Paired-Samples T-Tests and Mann-Whitney tests were used for determining differences in samples from the blank controls taken at t = 0 and t = 15 minutes, respectively. To determine differences in uptake rates between the different treatments, Paired-Samples T-Tests were used ($\alpha = 0.05$).

Results
It was observed that all coral colonies responded immediately to all treatments by capturing prey from the moment it was added to the chamber. No significant reduction in nauplii numbers was observed in the blank controls, except for IBBS. The IBBS were observed to stick to dead surfaces easily (both in blank controls and in incubations with corals). Due to this stickiness, the numbers of IBBS in the blank controls decreased by 14% within the 13 minute experimental interval. This was taken into account by subtracting this difference from the number of consumed IBBS in the experiments with corals.

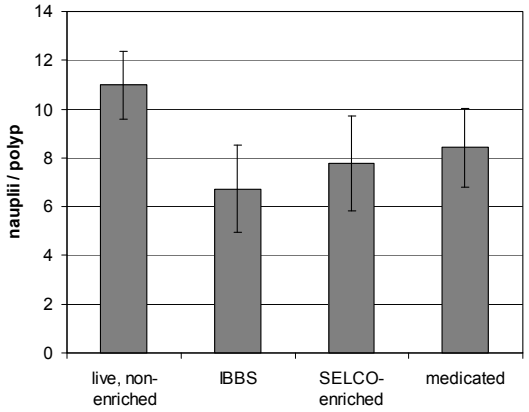

Figure 1. Average number of nauplii captured per polyp within the 13 minute incubation interval. Error bars indicate standard deviations (n = 24).

The average capture rates (expressed as nauplii captured per polyp within the 13 minute time

interval) for the different prey types were 10.98 (freshly hatched), 6.73 (IBBS), 7.77 (SELCO-enriched) and 8.42 (medicated) (Fig. 1). The uptake of freshly hatched, non-enriched nauplii was significantly higher than the uptake of the other prey types ($p < 0.001$). The reduction in capture rate was 38% for LBBS, 29% for SELCO-enriched nauplii and 23% for SELCO-enriched nauplii supplemented with antibiotics.

When normalized to organic carbon (Table 2), uptake per polyp was highest for medicated *Artemia*, which had a carbon content that was slightly higher than that of freshly hatched, non-enriched nauplii. Surprisingly, SELCO-enriched Instar II nauplii had a lower carbon content than freshly hatched, non-enriched nauplii. The measured carbon contents were comparable to literature data: Ohman (1987) reported a value of 0.5 µg C per nauplius, Evjemo and Olsen (1999) reported a value of 0.77-0.95 µg C per nauplius.

Table 2. Organic carbon content per individual for live *Artemia* products and calculated mean organic carbon uptake per polyp within the 13 minute incubation interval.

Treatment	Organic carbon content (µgC)	Organic carbon uptake (µgC/polyp)
Live, non-enriched	0.30	3.29
SELCO-enriched	0.25	1.94
Medicated	0.42	3.54

Discussion

Live Artemia *nauplii versus Instant Baby Brine Shrimp*

Our study showed some limitations of Instant Baby Brine Shrimp for feeding corals in captivity. The scleractinian coral *Galaxea fascicularis* preferred live, non-enriched *Artemia* nauplii over IBBS. Besides, IBBS tend to precipitate and stick to other surfaces. We conducted a similar experiment on another coral species, *Seriatopora caliendrum*, which also significantly preferred freshly hatched live nauplii over IBBS, IBBS uptake rates being on average 80% lower. However, the fact that IBBS are captured by both coral species demonstrates that the product is in principle suitable for coral culture.

In order to improve the IBBS product for feeding corals, it is important to understand why live nauplii are preferred. Live zooplankters are able to swim and have been reported to show an active escape response when approaching a predator tentacle (Trager et al. 1994; Heidelberg et al. 1997). From this point of view, one would expect that IBBS are captured more easily by the corals than live nauplii. But, apparently, IBBS does not trigger the feeding response of the corals to the same extent as live nauplii do. Corals kill their prey by nematocyst discharge, a process that is controlled by both chemical and mechanical factors (Thorington and Hessinger 1988). With respect to the latter, Heidelberg et al (1997) suggested that prey items approaching tentacles with a higher velocity would be captured more easily. When feeding corals with IBBS, it may therefore be beneficial to increase the water flow in the aquarium. This may also reduce the loss of IBBS due to precipitation and stickiness.

The possibility that IBBS lack a chemical trigger can also not be ruled out. Live zooplankters excrete small amounts of amino acids, which have been reported to trigger the feeding response in coral polyps (Mariscal et al. 1968). Lehman and Porter (1973) showed that addition of proline, glutamic acid, aspartic acid and arginine stimulates corals to ingest pieces of filter paper. In this light, there are possibilities to improve Instant Baby Brine Shrimp.

Enriched and medicated nauplii

Although captured with a lower efficiency than non-enriched nauplii, the SELCO-enriched and medicated nauplii were readily consumed by the corals, showing that *Artemia* nauplii can effectively be used as a vector to supply the corals with specific components such as antibiotics or probiotics.

This result provides a useful first step towards development of validated procedures to treat diseased corals with medicated *Artemia*, in analogy with Chair et al (1996), who conducted successful experiments with these antibiotics in fish and shrimp. However, successful application of this technique to corals will depend on several factors that remain to be studied, such as the digestion rate of the antibiotics in the gut of the polyps and the localization of the antibiotics' target. Oral administration of antibiotics may not be the most optimal way to treat diseases that primarily affect the outer cell layer of the coral tissue. In addition, diseased corals may cease their feeding activity.

Nevertheless, the possibilities for coral-specific enrichments are not limited to the addition of antibiotics. Corals are known to be dependent on heterotrophic feeding in order to obtain specific components needed for growth. For example, Allemand et al (1998) suggested that in *Stylophora pistillata*, heterotrophic feeding was the main source for aspartic acid, which is a main constituent

of the skeletal organic matrix of this species. Specific enrichment of *Artemia* nauplii with aspartic acid may reduce the amount of food needed to breed these corals.

Differential Expression of Soluble and Membrane-bound Proteins in Soft Corals (Cnidaria: Octocorallia)

E. Tentori*, M. Thomson

School of Biological Sciences, The University of Sydney, NSW 2006, Australia
* present address: ERT Scotland Ltd, Research Park South, Heriot-Watt University, Edinburgh EH14 4AP, UK

Abstract. Current understanding of the ecological role of corals is largely based on extrapolations of physiological processes studied on coral colony fragments as model experimental units. Due to their modular nature, these organisms are assumed to be structurally and functionally homogeneous. Here we address this assumption in an investigation of the distribution of proteins in soft coral tissue regions. This is the first study comparing variations of protein content and protein profiles within colonial cnidarians. *Sarcophyton* sp and *Capnella gaboensis* specimens were sectioned into colony regions with different physiological potential, based on their proximity to endosymbiotic algae and/or direct contact with the external medium. The tissues were homogenized in either 'NP40 buffer' a solution efficient at extracting membrane-bound proteins, or 'Tris buffer' which is efficient at extracting soluble, cytosolic proteins. SDS-PAGE analysis of proteins showed significant intracolonial differences of protein content ($p<0.05$) and differences of protein profile ($p<0.05$). This investigation indicated that the specific proteins have a different pattern of distribution ($p<0.05$) when the tissues are processed using NP40 or Tris buffers. Different spatial expression of proteins suggests regional functional specialization within the structurally repetitive units of these modular organisms.

Keywords. Octocorals, protein, electrophoresis, modular organisms.

Introduction

Whole protein content is routinely measured as an index of physiologically active biomass of cnidarians in numerous investigations such as skeletal and cellular growth (Goreau 1959; Velimirov and King 1979; Barnes 1985; Allemand and Grillo 1992; Tentori et al. 2004); coral-zooxanthellae interactions (Michalek-Wagner and Willis 2001); and expression of specific proteins (Snyder and Rossi 2004; Phelan et al. 2006). Edmunds and Gates (2002) considered soluble protein an acceptable normalizing trait that reflects the spatio-temporal variability of biomass. Tentori and Allemand (2006) questioned the implicit assumptions that protein is equally distributed through coral tissues and interacts uniformly with all the tissues of the experimental coral specimens. Indeed, seasonal and stress-related variability in the protein content of colonial cnidarians has been shown in recent studies (Barneah et al. 2005; Ravindran and Ragukhumar 2006). Further research on the chemical nature of colonial cnidarian tissues is needed to appreciate their functional complexity.

To understand the way the tissues of coral colonies interact with the environment, we need to consider their physical organization. Hard and soft corals adopt a range of growth forms from fine-arborescent to thick-massive structures. Hard and soft coral specimens of comparable dimensions are common occurrence in healthy Indo Pacific reefs, but their internal compositions are remarkably different. All cells in the stony coral body are located close to the external medium and to their symbiotic algae; the tissues spread generally less than 1 mm thick over the skeleton (Quan-Young and Espinoza-Avalos 2006). The widely used water pik method developed by Johannes and Wiebe (1970) amongst coral researchers in the analysis of coral tissues highlights the assumed even distribution of functional components. By contrast, in the soft coral body the polyps form a mass several centimetres thick (Chevalier et al. 1984); the distribution of zooxanthellae is limited by penetration of light into the external tissues (Chin 1996). Clearly, the soft coral morphology increases the resolution needed to study the functional variability of tissues in the modular nature of colonial cnidarians.

The aim of this study is to investigate the spatial distribution of proteins in soft corals. Two zooxanthellate soft corals were studied: *Sarcophyton* sp and *Capnella gaboensis*. Colony regions with different potential of interaction with their endosymbiotic algae and the external medium were analyzed, we refer to these as *functional regions*. We hypothesized that the identified functional regions

would be equipped with different proteinic component. Specific protein bands obtained from tissue homogenates processed under different methods were compared.

Materials and Methods

The experimental organisms

Sarcophyton sp. was collected at 1-3 m depth, 5km off Broome, Western Australia and maintained for two weeks in aquarium conditions: 35 ppt salinity, light intensity of 100 µmol photons m^{-2} s^{-1}, 26°C temp, fed once a week, 30% water exchanged weekly. *Capnella gaboensis* was collected at Fairlight, on the Sydney coast, at 6 m depth, this coral was processed on the day of collection.

Preparation of samples

Tissue samples from various functional regions of one *Sarcophyton* sp. colony and one *C. gaboensis* colony were sectioned as shown in Fig. 1A-B. The tissue homogenates were treated with two buffer solutions: NP40 buffer (40 mM Tris, pH 7.4, 1% Nonidet NP-40, 0.25% cholic acid, 150 mM NaCl, 1mM PMSF, 1 mg ml^{-1} aprotinin, 1 mM NaF) that solubilises membrane-bound proteins; and Tris buffer (40 mM Tris, pH 7.4, 10 mM EDTA, 1 mM PMSF, 1 mg ml^{-1} aprotinin), that solubilises cytosolic water-soluble proteins. Coral samples ranging from 0.2 to 0.9 g wet weight were homogenized on ice, in 0.5 ml of one of the buffer solutions using a Teflon grinder and kept for 30 min in ice and spun at 10,000 rpm, 4°C for 1 min. The coral extracts were stored at –20°C until time of analysis.

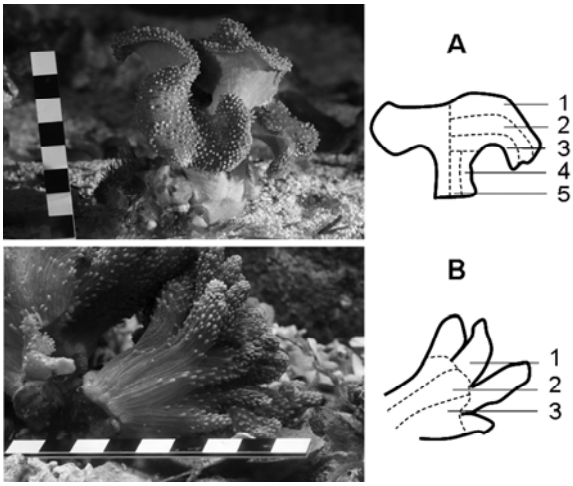

Figure 1. Soft coral colonies and functional regions investigated. (A) *Sarcophyton* sp.: capitulum upper (1); capitulum middle (2); capitulum lower (3); stem surface (4); stem subsurface (5). (B) *C. gaboensis*: lobe (1); stem surface (2), stem subsurface (3). Ruler marks = 1 cm.

Analysis of proteins

Total protein content was measured by colorimetry with bicinchoninic acid (BCA) as standard, and read at 526 nm using a microplate reader. Proteins were analysed by sodium dodecyl sulphate polyacrilamide gel electrophoresis (SDS-PAGE). Molecular marker and 3 replicate samples were loaded onto 12% Tris Glycine gels using 4 % stacking gel and run at 200V for approximately 1 h. The analysis of gel images was performed using the public domain NIH Image program (http://rsb.info.nih.gov/nih-image/). Using as a reference a molecular ladder, selected bands were analyzed and compared across all the resulting gels.

Experimental set up

Total protein content was analyzed in duplicate samples. The electrophoretic analysis was performed in triplicate samples. Two protein bands (approximate MW of 54 and 35 kDa) were compared amongst all treatments in each coral species. The effects of buffer and functional region on these two main specific protein bands were tested by one-way ANOVA.

Results

Intracolonial distribution of proteins

The analysis of tissues showed decreasing protein concentrations from distal to proximal region of the colony and from surface to subsurface of the stem (Fig. 2A-B). The difference of protein content between regions was highly significant in both coral species (*Sarcophyton* sp ANOVA $p<0.001$; *C. gaboensis* ANOVA $p<0.001$). Tissue extracts prepared with NP40 and with Tris buffers showed similar general trends of variation of whole protein content. The two buffers produced a statistically significant difference of protein yield in *C. gaboensis* (ANOVA $p<0.01$) but not in *Sarcophyton* sp (ANOVA $p>0.05$).

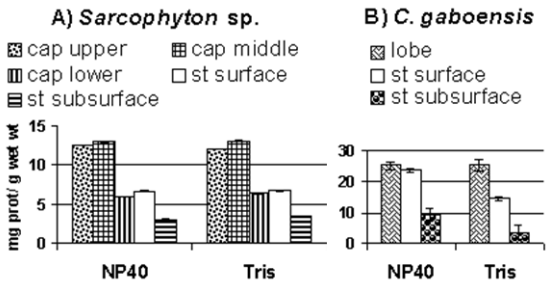

Figure 2. Total protein content in regions of the coral colony processed with NP40 and Tris buffers (n=2). (A) *Sarcophyton* sp. (B) *C. gaboensis*. Abbreviations: cap = capitulum; st = stem (mean ± 1 sd).

Extraction of specific protein bands

SDS-PAGE on coral tissue extracts prepared with NP40 and Tris buffers produced at least 12 protein bands in the molecular weight range 216 to 7 kDa as revealed by Coomassie Blue (Fig. 3A-B). The protein bands with approximate molecular weights of 54 and 35 kDa and three light bands closely set in the range 17 to 7 kDa showed the greatest contrast between the protein profiles obtained by the two methods of extraction. The 54 and 35 kDa bands were analysed by densitometry

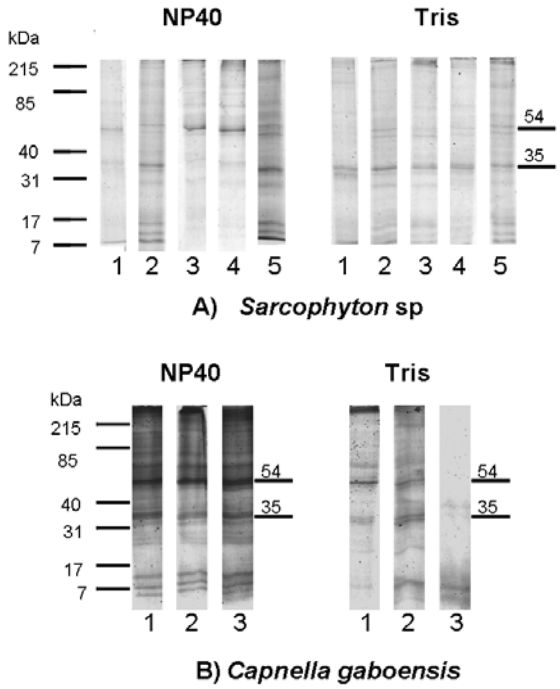

Figure 3. SDS-PAGE protein profiles of soft coral extracts. (A) *Sarcophyton* sp. Regions indicated by tracks: 1 = capitulum upper; 2 = capitulum middle; 3 = capitulum lower; 4 = stem surface; 5 = stem subsurface. (B) *C. gaboensis*. Regions indicated by tracks: 1 = lobe; 2 = stem surface; 3 = stem subsurface.

The density of specific protein bands 54 and 35 kDa was highly variable throughout both coral species. The method of protein extraction also produced significant variation in the content of these protein bands (Figs. 4-5). There were 3 functional regions in which one of the specific protein bands was not detected by one of the methods (54 kDa *Sarcophyton* sp. capitulum upper region in Tris; 35 kDa *Sarcophyton* sp. capitulum lower region in NP40; 54 kDa *C. gaboensis* stem subsurface region in Tris). The interaction between regions and extracts was significant in all cases except for protein band 35 kDa in *C. gaboensis* (see Tables 1 and 2).

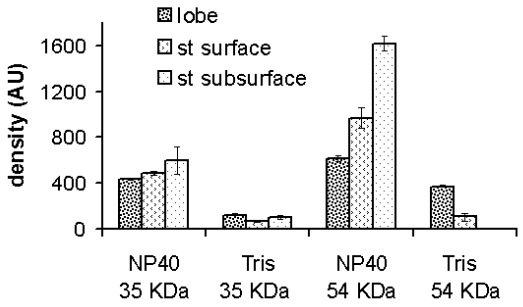

Figure 5. *C. gaboensis*. Comparison of two protein bands obtained by SDS-PAGE in coral samples prepared with NP40 and Tris buffers (n=3). (A) Protein band 54 kDa; (B) Protein band 35 kDa. Density of bands is reported in arbitrary units (mean ± 1 se).

Discussion

This investigation contains the first comparative data of whole protein content as well as specific protein bands in tissues from various regions of soft coral colonies. The application and comparison of two different buffer solutions in the extraction of cnidarian proteins is also tested for first time.

In any organism, protein half-lives range from minutes to months depending on their function and location; their continuous renewal is the basis for biological adaptation (Hawkins 1991) yet few studies have considered the spatial variation of proteins in colonial cnidarians. The variation of protein content between polyp and stem regions in the soft corals *Sarcophyton ehrenbergi* measured as elemental carbon-to-nitrogen ratios (Tentori et al. 1997) and *Litophyton arboreum* measured as sclerite-to-protein weight ratios (Tentori et al. 2004) indicate that distal tissues are richer in protein than are proximal tissues. Protein content (measured as protein-to-biomass weight ratios) of soft corals reported in the present study confirm those results. Furthermore, our data

show significant differences in protein content throughout the colony. These data are indicative of different functional potential amongst the tissues involved.

Variability of Specific Proteins

Research on protein diversity of colonial cnidarians highlights the dynamic metabolism of these organisms. Electrophoretic protein profiles have been generated for various cnidarian species identifying stress proteins associated with heat shock (Black et al. 1995; Sharp et al. 1995); space competition (Rossi and Snyder 2001); dietary changes (Rossi et al. 2006); zooxanthella acquisition (Barneah et al 2005); and microbial infection (Ravindran and Raghukumar 2006). In these studies two important aspects of the temporal variability of specific proteins in colonial cnidarians are appreciated: 1) the variation of specific proteins does not match the trend of variation of whole protein content (Black et al 1995; Ravindran and Raghukumar 2006; Rossi and Snyder 2001; Rossi et al 2006); 2) a change of specific proteins can be induced within hours in the laboratory or within several weeks under natural environmental conditions (Black et al 1995; Sharp et al. 1995; Rossi and Snyder 2001; Barneah et al. 2005).

The spatial variability of proteins in cnidarians is less well documented. Rossi and Snyder (2001) reported the variation of stress proteins amongst tentacles of single polyps in anemones and corallimorpharians, they pointed out the differences between whole-organism and selected-tissue responses. Given the apparent morphological simplicity of colonial cnidarians, their protein analysis is commonly performed on whole experimental specimens or unspecified fragments of those specimens. We suggest that detailed knowledge of the spatial variability of proteins within the cnidarian colony tissues could increase the resolution of the experimental response sought in physiological investigations.

In the present study, the protein bands, of approximate molecular weights of 54 and 35 kDa, stand out as a common feature in both *Sarcophyton* sp and *C. gaboensis* suggesting their involvement in a cellular activity or structural requirement common to both species. Yet the variable abundance of these protein bands indicates contrasting needs amongst the various functional regions analysed. Our results are evidence of tissue specialization in organisms that have been largely regarded as morphologically and functionally uniform.

Soluble and membrane-bound protein distribution

Specific protein analysis is commonly performed on the soluble fraction of tissue homogenates processed either in Tris-HCl (Black et al 1995; Sharp et al 1995; Bythell et al 1995; Barneah et al 2006) or in phosphate buffers (Harithsa et al 2005; Ravindran and Raghukumar 2006; Takeda et al 2000; Rossi and Snyder 2001; Rossi et al 2006). Hashimoto et al. (2005) analysed both soluble and insoluble proteins obtained from Tris extracts of anthocodia (distal region of the polyp) of the soft coral *Clavularia viridis*; they demonstrated a different protein profile for each of the two fractions. Our results agree with that general finding.

The use of NP40 allows detection of membrane-bound proteins. To our knowledge, this is the first application of NP-40 to obtain proteins from cnidarian tissues. Our study revealed a significant difference of the protein profile of *Sarcophyton* sp and *C. gaboensis* depending on the extraction buffer used and colony region analysed (Tables 1 and 2).

The existence of different tissue regions in soft coral colonies is acknowledged in early taxonomic descriptions highlighting the site-specific shape of their sclerites (Verseveldt 1977). Furthermore, there is evidence of functional gradients in the soft coral body associated with feeding (Schlichter 1982; Schlichter et al. 1983), secondary metabolite production (Maida et al. 1993; Van Alstyne et al. 1994), gastrovascular circulation (Gateño et al. 1998), cell growth and tissue repair (Tentori et al. 2004), characteristics that are no doubt linked to the protein profile of the tissues involved. We suggest soft corals as model organisms that offer a natural experimental setting to enhance spatial resolution in cnidarian physiology.

Practical applications of contaminant-free *Symbiodinium* cultures grown on solid media

N. Soffer, P.D.L. Gibbs, A.C. Baker

Division of Marine Biology and Fisheries, Rosenstiel School of Marine and Atmospheric Science, University of Miami, 4600 Rickenbacker Causeway, Miami 33149, Florida, USA.

Abstract. Symbiotic dinoflagellates in the genus *Symbiodinium* are critical to the success of scleractinian reef corals in shallow tropical seas. These symbionts are commonly isolated from hosts and cultured separately in liquid media (f/2 or ASP8a), but initial isolations can be prone to abundant contaminants that can persist long-term in culture. To help remove these contaminants, we developed a solid growth substrate composed of 1% agar in f/2 medium, supplemented with a variety of antibiotics, to help isolate individual clones and establish new "axenic" cultures. We found that an antibiotic cocktail of kanamycin (50 μgmL^{-1}), ampicillin (100 μL^{-1}) and streptomycin (50 μgmL^{-1}) was the most effective at eliminating visual signs of contamination without apparent harm to a variety of *Symbiodinium* in culture. Photophysiological measurements of *Symbiodinium* grown on agar plates, taken using an Imaging Pulse Amplitude Modulated (I-PAM) fluorometer, were comparable with those grown in liquid f/2 medium, both with and without antibiotics. *Symbiodinium* cultures grown on solid substrates supplemented with antibiotics are useful for: (1) isolating individual cells or clones for subsequent applications; (2) establishing and maintaining "axenic" cultures, free of observable contaminants; and (3) directly comparing (on the same plates) the photophysiology of different cultures using an I-PAM fluorometer.

Key words: *Symbiodinium*, coral, physiology, culture, I-PAM fluorometry

Introduction

Scleractinian reef corals depend on symbiotic dinoflagellates in the genus *Symbiodinium* for their metabolic needs (Muscatine 1967). Currently, 8 clades (A-H) are recognized, each of which contains multiple sub-types (Coffroth and Santos 2005; Pochon et al. 2006). This genetic diversity could provide a mechanism for corals to adapt or acclimatize to environmental changes, provided that genetic diversity in the symbionts translates to different physiological capabilities for the coral host. Studies of symbiont photophysiology may therefore help provide insight as to whether symbiont diversity can help corals survive environmental change.

Cultures of *Symbiodinium* isolated from different invertebrate and protist hosts are usually established and maintained in liquid media (f/2 or ASP8a), but are often prone to abundant contaminants that can be difficult to remove. Antibiotics and repeated dilutions have been used to eliminate some contamination; however, this process is time consuming and inconsistent (Anderson and Kawachi 2005). In addition, isolating a single cell of interest is difficult using traditional methods, which involve using capillary action to isolate a cell in an ultrafine glass pipette (Guillard 2005). Agar blocks set onto liquid media have previously been used to select for single transgenic *Symbiodinium* cells, but this method required daily additions of fresh liquid media and antibiotics (ten Lohuis and Miller 1998).

Agar plates have been routinely used for culturing microalgae, but only rarely for dinoflagellates (Schoenberg and Trench 1980; Guillard 2005). Growing *Symbiodinium* spp. on agar plates resolves some of the issues mentioned above, and agar plates with host homogenate have been successfully used to isolate new types of *Symbiodinium* in clades C and D from the giant clam, *Tridacna crocea* (Isikura et al. 2004).

Here we show how growing *Symbiodinium* on a solid medium of 1% agar, supplemented with f/2 medium and a combination of antibiotics, helps isolate single cells, eliminate microbial contaminants, and facilitate photophysiological measurements using an Imaging Pulse Amplitude Modulated Fluorometer (I-PAM: Walz, Inc., Effeltrich, Germany).

The I-PAM is a convenient tool for measuring and visualizing photosynthetic parameters such as effective quantum yield (α), electron transport rate (ETR), and quantum yield of Photosystem II (as the ratio of variable fluorescence to maximum fluorescence, or F_v/F_m). Together, these parameters

have proven useful in assessing photosynthetic response to light limitation, the ability of symbionts to tolerate changes in light over a short period of time, and overall photosynthetic efficiency (Rolfe and Sholes 1995; Ralph and Gademann 2005).

Material and Methods

Maintenance of algal cultures

Algal cultures, supplied by S. Santos (Auburn University, USA), were maintained in liquid f/2 media or solid media (described below). Incubator settings were 25.5°C, 12h L/D cycle. Liquid media were changed monthly. Cultures were re-plated monthly, while still keeping the original plates.

Production of agar plates

A solid growth medium was made by autoclaving 1% bacto-agar (Difco) in 20 mL filtered seawater. Once the mixture had cooled to <55°C, 0.4 mL of 50X f/2 medium (Sigma) was added, and the mixture was then poured onto plates (100mm diameter) and allowed to cool. After 24h, 10-30 µL aliquots of 19 different *Symbiodinium* cultures were spread onto the plates (Table 2). All plates were sealed with parafilm.

Testing resistance to antibiotics

After one month growing on the solid medium, we tested the effectiveness of antibiotics in removing contaminants in 10 cultures with the highest levels of microbial contamination. With a bacterial loop, we removed approximately 10 µL of *Symbiodinium* from each plate (together with their associated contaminants), mixed this with 200uL filtered seawater, and spread this inoculate onto fresh plates to which we added a variety of antibiotics (Table 1). These plates were prepared as outlined above, with the antibiotics added with the f/2 medium as the agar cooled. We also inoculated control f/2 plates with no antibiotics. The relative growth of microbes and *Symbiodinium* was recorded after 3, 7 and 14 days, and periodically for 5 months thereafter.

Elimination of contaminants

Symbiodinium colonies growing on the antibiotic treatment showing the least contaminants (a cocktail of kanamycin, ampicillin and streptomycin, "KAS", see Table 1) after 2 weeks were picked with a bacterial loop and re-streaked onto fresh KAS-treated plates. After 1-3 weeks, if contamination persisted, single *Symbiodinium* cells were picked from plates, using a straight wire under a microscope, and then re-streaked onto new plates.

Photophysiological comparisons of symbionts

We compared the photophysiological parameters of *Symbiodinium* culture Zs (in clade A) grown in liquid f/2 (n=5) with the same culture grown on f/2 plates (n=2) and f/2 plates with KAS (n=5). Cultures were grown from contaminant-free clones picked from a KAS plate.

Table 1: Growth of *Symbiodinium* and bacterial contaminants after 3-14 days under different antibiotic applications: + medium growth, ++ high growth, – low growth, 0 no visible growth.

Growth of *Symbiodinium* and bacterial contaminants under different antibiotic

None	0	+	+

I-PAM measurements were taken after 19 days. Cultures were dark adapted for 20 min before induction curves were measured, and then returned to the incubator for 20 min before rapid light curves were measured.

The maximum electron transport rate (ETR_{max}) and the effective quantum yield (α) were calculated by fitting rapid light curves to a double exponential decay curve in Sigma Plot (Ralph and Gademann 2005). Photosynthetic efficiency (F_v/F_m) was obtained from induction curves. For solid plates, we compared photosynthetic parameters extracted from the whole plate with those obtained from the average of 5 random points on the plate. For the liquid medium we measured parameters from the whole culture (Fig. 1). Data were compared using a one-way ANOVA followed by post-hoc Tukey-Kramer HSD tests if significant differences were found.

Results

Resistance to antibiotics

Most liquid stock cultures are prone to high levels of microbial contamination that cannot be controlled with a single antibiotic application. Cultures maintained on f/2 plates with KAS remained free of contaminants for at least 5 months, with no visual signs of bacterial growth. Agar plates with KAS show the highest relative growth for symbionts but the lowest bacterial growth (see Table 1). In addition, bacterial growth was easily reduced by physically removing symbionts from bacteria by picking clones and re- streaking. There was 100% mortality for both symbionts and bacteria on chloramphenicol plates after 3 days. Kanamycin and G418 had a high relative growth for at least one bacterial morphotype (based on colony shape and color), even at 3 $mgmL^{-1}$. Some cultures on KAS plates still showed some bacterial contaminants after 5 months; however, contamination was approximately an order of magnitude less on a per-cell basis than the same culture grown in control f/2 media (solid or liquid) with no antibiotics (see Table 1).

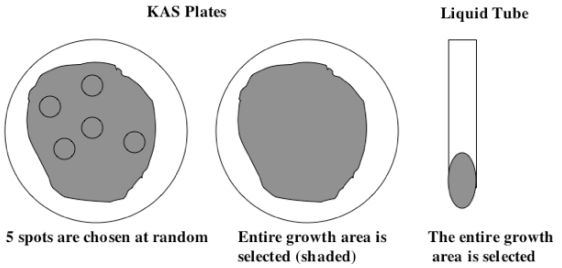

Figure 1: Two methods for IPAM measurements were used: selecting 5 spots at random of growth area, or selecting the entire growth area referred to as "whole plate." The entire liquid area (20 ml) was selected for liquid tube I-PAM measurements. Lids were removed from plates under the IPAM.

Many types of *Symbiodinium* can be grown on agar plates (Table 2), but in this study, members of clades A and C had the highest growth rates. Most of the 19 *Symbiodinium* types we tested on agar plates showed positive growth on this medium. Some were difficult to maintain long-term, particularly those in clade D. However, the majority of cultures were easily maintained on agar plates for >5 months and repeatedly used to create new stocks.

Photophysiological comparisons

The two sampling methods for taking I-PAM measurements on plates (5 random spots vs. whole plate), produced comparable mean values of ETR_{max} and α (P> 0.7292 and P> 0.9998, determined by a one- way ANOVA, respectively), both on f/2 only plates and f/2 + KAS plates. Further, following the ANOVA test, the F_v/F_m, values as shown by a post hoc test(Tukey-Kramer HSD test) displayed no significant difference within the same type of plates for either of the two sampling methods (Fig. 2). In contrast the post hoc test did show a significant difference between plates and liquid tubes for F_v/F_m Variability in all parameters was less using the "random spot" method, compared to "whole plate" method (error bars in Fig. 2). F_v/F_m values were significantly lower for solid media on plates,

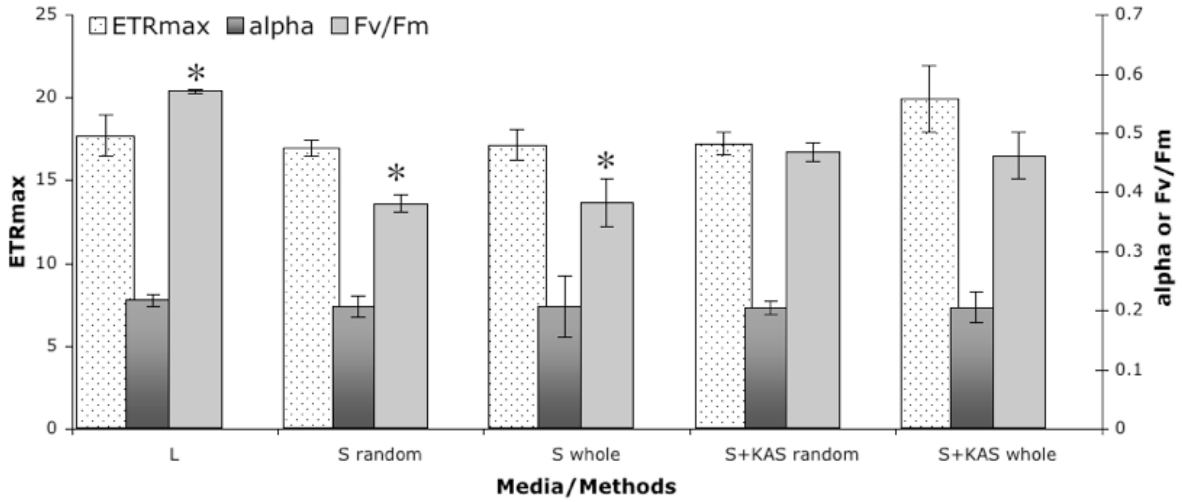

Figure 2: Comparison of photophysiological parameters (ETR_{max}, α and F_v/F_m) for *Symbiodinium* culture Zs (clade A) grown on three media types: L (liquid f/2), S (solid agar f/2) and S+KAS (solid agar f/2 supplemented with KAS) (whole plate and 5 spots). Error bars represent standard error of the appropriate mean value. A Tukey-Kramer HSD test revealed significant differences between treatments for parameters marked with an asterisk (*). Values not marked with an asterisk are not significantly different among methods and media.

compared to liquid media in tubes (P>0.0007; Fig. 2). All other comparisons showed no statistical differences from each other.

Discussion

General plate applications

Our results indicate that growing *Symbiodinium* on sold agar plates supplemented with f/2 and antibiotics is useful for the following applications: isolating single cells and clones, purifying cultures and reducing contamination, and undertaking comparative photophysiological studies. Current techniques to remove microbial contamination include repeated antibiotic doses applied on a weekly, or even daily, basis. This can be expensive and time-consuming. Using f/2 + KAS plates, the use of antibiotics is limited to 2-3 applications over a >5 month period. Transferring symbionts to new media is only necessary when plates begin to dry out (which typically occurs after a few months), and is mainly done as a precautionary step to avoid dessication and and self-shading of cultures. In addition, microbial contamination can be readily detected (by eye or microscope) and removed. In liquid media, contamination is much harder to detect, and can be done only by determining relative "cloudiness." Our cultures remained completely free of any visible contamination (via microscope) for >5 months on the same KAS plates, and remained sufficiently viable to establish new cultures at the end of this period. A potential pitfall of any plate-based method is local depletion of either antibiotics or nutrients over time, leading to mortality or decreased growth rates. More studies are needed to determine the long-term viability of *Symbiodinium* maintained on the same plate. Another potential problem is that sub-culturing from plate to plate may result in genetic drift. This might be reduced by mixing multiple clones picked from plates to establish new cultures.

Table 2: Types of *Symbiodinium* grown on agar plates, with their invertebrate host and geographic location. * denotes contaminate free cultures for over 5 months, + denotes slow growing, - denotes low amounts of contaminants.

An additional potential application of agar plates and antibiotics is the selection of genetically transformed *Symbiodinium*. Chloramphenicol plates were very effective in killing *Symbiodinium* (and bacteria), and might therefore be used as means of selecting for successful transformants.

I-PAM specific plate applications

ETR_{max} and α were not significantly different for tubes or plates (with or without antibiotics), indicating that the plate method is equivalent to the traditional liquid tube method for rapid light curve measurements. We recommend that the "whole plate" method be used for large-scale experiments with >5 replicates, since the method is more rapid while still yielding results that are comparable to the "random spot" method. For studies with few replicates, the "random spot" method should be used to reduce error.

We found plates easier to manipulate than liquid media since there was no need to separate clumps and the entire plate could be visualized using the I-PAM. Additionally, individual clones grown on plates can be selected by the I-PAM as "Areas of Interest", allowing within-population comparisons to be made. In liquid media, where symbiont populations are mixed, these distinctions cannot be made.

Solid plates also allow clones with certain characteristics (such as high growth rate, varying F_v/F_m rates etc) to be selected from a population. Finally, different types of *Symbiodinium* can be compared side-by-side on the same plate (we have cultured up to 4 cultures in different quadrants of the same plate) for physiological comparisons among types. This helps reduce error within treatments.

Abstract. Cnidarian-algal symbioses are important in sustaining coral reef ecosystems. Little is known about how these associations respond ecologically and evolutionarily to environmental change. We examined the diversity of zooxanthellae populations in two morphotypes of *Porites panamensis* in the southern Gulf of California. Additionally, we analyzed the host genetic information by allozyme electrophoresis in order to demonstrate if the species of symbiont corresponds with the genotype and/or morphotype of the host individual. The specimens (N = 20) were collected from shallow coral communities (1-2 m). *Symbiodinium* C66a associated with columnar colonies while C66 occurred commonly in colonies with mounded or massive morphologies. Both colony forms associated with C1. Higher allelic diversity and different symbiont clades were found in columnar colonies, relative to massive colonies in the same habitat. Certain host genotypes associated specifically with a particular *Symbiodinium* type. These preliminary findings indicate that host-symbiont co-evolution is important in shaping partner combinations and that the mode of symbiont acquisition by maternal or vertical transmission facilitates this process.

Key words: host-symbiont specificity, *Symbiodinium*, host-genetic data, species complex, scleractinian coral

Introduction

Partner specificity is important to the biology of all reef corals maintaining obligate associations with endosymbiotic dinoflagellates in the genus *Symbiodinium* (zooxanthellae) (Baker 2003; Stat et al. 2006). Ecological and physiological studies indicate that tolerance to low and/or high light and temperature differs among *Symbiodinium* (Iglesias-Prieto et al. 2004; LaJeunesse et al. 2008). Hosting a particular symbiont may therefore determine the longevity of the colony when exposed to episodes of stress. Of critical interest is determining how changing environmental conditions affect the stability and evolution of these partnerships over time (LaJeunesse 2004; Stat et al. 2006). Initial analyses of corals in the Gulf of California (GC), have showed that they maintain highly specific and stable associations, despite wide seasonal fluctuations in light and temperature (Iglesias-Prieto et al. 2004; LaJeunesse 2004; LaJeunesse et al. 2008).

The coral *Porites panamensis* is widely distributed in the Eastern Pacific. In the Gulf, this species has two colonial morphologies with slight differences in corallite morphology (Ketchum and Reyes-Bonilla 2001), ability to recover from physical damage (Paz-García and Reyes-Bonilla 2006), and vertical distribution (López-Pérez et al. 2003; Paz-García and Reyes-Bonilla 2006), and appear to be genetically distinct (Paz-García et al. 2008b). These data suggest that several factors could explain the variation observed in both morphotypes (Paz-García et al. 2008b). *Porites panamensis* harbors different symbiont types (LaJeunesse et al. 2008), but it is unknown whether the distribution of these symbionts relates to host-morphotype. Our aim was to examine the diversity of *Symbiodinium* in these two morphotypes of the coral *P. panamensis* in the southern Gulf of California. Additionally, We analyzed the host genotypes by allozyme electrophoresis in order to demonstrate if the species of symbiont corresponds with the genotype and/or morphotype of the host individual. This study is among the first to provide evidence that host genotype dictates the distribution of different symbiont types.

Material and Methods

Field Work. The collections were conducted in May 2006 in two locations in the southern Gulf of

California, Mexico (Fig. 1). The columnar morphotype of *P. panamensis* is more prevalent at Punta Gaviotas, the massive one at Punta Galeras (Paz-García and Reyes-Bonilla 2006). The specimens (n = 10 for each morphotype) were colleted from shallow coral communities (1-2 m).

Figure 1: Map showing the locations, in the south of the Gulf of California.

Symbiont Identification. Coral fragments were stripped of tissue using an airbrush and the symbiont cells isolated as described by LaJeunesse et al. (2003). Algal pellets were transferred to 1.5 mL microcentrifuge tubes and preserved in 20% dimethylsulfoxide (DMSO), 0.25 mol L^{-1} ethylenediamenetetraacetic acid (EDTA), in sodium chloride-saturated water solution (Seutin et al. 1991). The genetic identity of the *Symbiodinium* populations in each sample was later analyzed via PCR-denaturing gradient gel electrophoresis (DGGE) of the ITS regions 1 and 2 as described by LaJeunesse et al. (2008).

Host genetic analysis. We conducted a coral tissue extraction as described by Paz-García et al. (2008a). We determined the concentration of total proteins from each sample by Bradford's method (Bradford 1978) and 25 μg were used for the analysis of each enzyme system. Allozyme analysis was carried out using polyacrylamide gels. Four enzyme systems were used: LGG (E.C.3.4.11.1), ME (E.C.1.1.1.40), GDH (E.C.1.4.1.3) and EST (E.C. 3.1.1.1).

To examine the differences between host morphotype and symbiont ITS type, we scored and compared the frequencies of allozyme alleles between colonies that were either columnar or massive and/or associated with C66, C66a, or C1. Host allelic and genotype frequencies were tested by the Markov chain method (Raymond and Rousset 1995). Host unbiased genetic distance (Nei 1978) was used to carry out cluster analysis among clade groups.

Results

Six colonies of columnar *P. panamensis* associated with *Symbiodinium* C66a while the other four colonies harbored C1. The distribution of these combinations appeared random. All 10 shallow massive colony morphotypes collected from Punta Galeras associated with C66 (Fig. 2). A single symbiont type was detected in each colony analyzed.

During the animal genotyping, two to four alleles were found for each allozyme locus analyzed. Higher allelic diversity was found in columnar colonies relative to massive colonies (Fig. 3). One genotype of locus LGG-1 and three genotypes of locus ME-1 were observed in colonies associating with a particular symbiont type (Table 1). Significant differences in host allelic and genotype frequencies were determined by Markov chain analyses of columnar C1 and massive C66 colonies (Table 2), but allelic and genotype diversity in colonies with C66 and C66a were not statistically different or were columnar colonies with C66a or C1 (Table 2). The relationship between host-genotype and symbiont type was supported by cluster analysis based on host Nei's unbiased genetic distance that showed massive colonies with C66 and columnar colonies with C66a clustered together before joining columnar colonies hosting C1 (Fig. 4).

Discussion

Inter-colony variability in symbiont type among colonies of *Porites panamensis* appears to be influenced by environmental and biological factors. Five different *Symbiodinium* types are known to associate with *P. panamensis* in the Gulf of California (LaJeunesse et al. 2008). Depth strongly influences the frequency of occurrence of particular symbionts in populations of host individuals. *Symbiodinium* C1 is prevalent among colonies living below 2 meters. At depths below 5 meters colonies are occasionally found associating with C75. Closely related C66, C66a, and C66b occur in *P. panamensis* living in shallow environments (0.5 and 1.5 m). These ecological patterns suggest that significant differences in physiology exist among Clade C *Symbiodinium* (Sampayo et al. 2008).

Columnar and massive morphotypes of *P. panamensis* also exhibit differences in vertical distribution throughout the Gulf (López-Pérez et al. 2003; Paz-García and Reyes-Bonilla 2006). Columnar colonies are more limited in their distributions to shallow habitats, typically 0.5 to 4.0 meters from the surface. While these data are limited, the presence of a particular symbiont does not explain this pattern of zonation.

Specific host-symbiont combinations involving *Symbiodinium* adapted to different light regimes may result in ecological zonation along an irradiance gradient (Iglesias-Prieto and Trench 1994; Iglesias-Prieto et al. 2004). This coral belongs to one of the few genera that produce eggs containing symbiont cells (Richmond and Hunter 1990; Glynn et al. 1994). Therefore, the presence of a high or low light-adapted symbiont may directly affect the differential success of larvae settling in deep or shallow environments. Further understanding of the physiological performances of these different host-symbiont combinations (holobionts) under different environmental conditions would help explain these ecological patterns.

There appears to be a close correspondence with symbiont identity and host genotype (Fig. 4). While the columnar or massive morphology does not appear to influence symbiont distribution, the presence of C66 or C66a in hosts with similar genotypes suggests that host genetic background is important to specificity. While external physical factors affect the symbioses in some hosts (Rowan et al. 1997), host-symbiont specificity plays a crucial role in dictating the distribution of certain partner combinations.

Thoroughly describing the ecological and geographic distributions of specific host-symbiont combinations is important for ultimately understanding co-evolutionary processes that occur between host and symbiont lineages. Associations with C1, C66 (a and b variants), and C75 are unique for Indo-Pacific *Porites* (LaJeunesse 2004). The evolution of unusual host-symbiont combinations is probably influenced by populations living for many generations in isolation while subjected to wide ranges in temperature and water clarity, as is characteristic of the northern Eastern Pacific. The presence of different symbionts among colonies of *P. panamensis* may provide the natural variation that may eventually be important in determining how these coral populations respond to selection pressures created by global warming.

Reference gene selection for qRT-PCR analysis of the Hawaiian coral *Pocillopora meandrina* subjected to elevated levels of temperature and nutrient

Marine Science Department, University of Hawai`i at Hilo, 200 West Kawili Street, Hilo, HI 96720

Abstract Quantitative reverse transcriptase PCR has several variables that need to be controlled for to obtain accurate estimates of gene expression data. The use of a single reference gene is a common method to normalize mRNA fractions and obtain reliable quantitative expression measures. However no universally appropriate reference gene exists that is constitutively expressed in all tissue types and all experimental conditions. One plausible solution for this problem is to use a set of reference genes for normalization that display minimal variation across all treatments. Past gene expression studies have often employed the use of a single reference gene. As the number of gene expression studies in reef-building coral is expected to increase, a set of suitable reference genes is needed for normalization. This study characterized the expression of five candidate reference genes for the scleractinian coral, *Pocillopora meandrina*, after chronic elevated nitrogen followed by increased seawater temperature. Two separate gene ranking assessment software programs were used to rank candidate genes by expression stability. The Brn1, β-actin, and 18S rRNA genes were the most stably expressed genes in *P. meandrina* subjected to long-term elevated nitrogen followed by an acute increase in temperature.

Key words: quantitative RT-PCR, gene expression, coral

Introduction

Quantitative reverse transcriptase polymerase chain reaction (qRT-PCR) is commonly used in biological applications for accurate quantification of gene expression changes between tissues, disease states or treatments (Bustin and Nolan 2004). Several variables between tissues or cells need to be controlled in qRT-PCR including the amount of starting material, differences between tissues or cells, quality of the RNA, and reverse transcription efficiency (Vandesompele et al. 2002). Various strategies have been used to control for the previously stated variations within qRT-PCR including techniques such as standardization to total RNA or to an endogenous reference gene.

Standardization to total cellular RNA can pose problems because it is difficult to quantify small amounts of RNA, and the variance present in reverse transcription and PCR efficiency are not considered (Huggett et al. 2005; Wong and Medrano 2005). In addition, the process of normalizing to total RNA assumes that rRNA is directly proportional to mRNA and does not vary between individuals, tissues, or cell cultures, or under different experimental conditions (Bustin and Nolan 2004). Alternatively, variations can be controlled for by normalization of the target gene to an endogenous reference gene. This comparison allows for a normalized expression value of the target gene that is independent of the quality and quantity of starting RNA and the efficiencies of the reverse transcriptase reactions (Huggett et al. 2005).

The most important criterion of appropriate reference genes in qRT-PCR is that these genes are expressed constitutively in cells irrespective of experimental conditions. In the past it was recommended that if it was not possible to find a constitutively expressed reference gene, it is an option to apply one of several frequently used genes as a control to normalize expressions of other genes against (Bustin 2000). In spite of this, there has been evidence that reference genes can be regulated under different conditions (Bustin 2000; Vandesompele et al. 2002). This means that although use of a referenced "stable" gene can be consistent for one experiment and one type of tissue, there is no universally perfect control gene that is perfect for all tissue types or treatments (Brunner et al. 2004; Vandesompele et al. 2002; Andersen et al. 2004).

qRT-PCR has been used in only a handful of anthozoan and hydrozoan gene expression studies (Yanze et al. 1999; Mitchelmore et al. 2002; Loram et al. 2007; Rodriguez-Lanetty et al. 2007). Many of these studies used a single reference gene to normalize the expression of their target genes. It was

recently reported that experiments that used a single reference gene to normalize expression of target genes let to erroneous quantifications (Vandesompele et al. 2002). Erroneous quantifications occur because gene expression of the control can result in unrecognized or unexpected changes (Vandesompele et al. 2002; Szabo et al. 2004). One probable solution for this problem is to use a set of reference genes for normalization that display minimal variation across the treatments included in the experiment (Vandesompele et al. 2002). There are several existing statistical analysis software programs to analyze the stability of reference genes (Pfaffl et al. 2001; Vandesompele et al. 2002; Andersen et al. 2004) and since their arrival they have been used with increasing regularity (Etschmann et al. 2006; Jorgenson et al. 2006; Nailis et al. 2006; Willems et al. 2006; Maccoux et al. 2007; Tang et al. 2007; Peltier and Latham 2008). In this study two popular statistical analysis software programs were used to identify the most stable candidate reference genes. The first program, GeNorm, calculates the most stable genes from a set of candidate reference genes based on the average pair-wise variation of a single gene compared to all other reference genes in the set (Vandesompele et al. 2002). The second program, NormFinder, evaluates the gene expression variability of reference genes within treatments compared to variation among treatments for each gene (Andersen et al. 2004). Both programs allow the ordering of candidate reference genes based on relative expression stabilities, referred to in this paper as "rank," through the use of a mathematical evaluation of expression data.

A recent study by Rodriguez-Lanetty et al. (2007) used GeNorm analysis to identify β-actin, ribosomal protein L12 and Poly(a) binding protein as three control genes determined to be stable from a cDNA microarray platform constructed from the sea anemone, *Anthopleura elegantissima*. However, to date, there has been no validated set of reference genes for qRT-PCR described for reef building corals. The aim of this study presented here was to evaluate a set of candidate reference genes, using GeNorm and NormFinder, in reef-building corals exposed to chronic levels of elevated nitrogen followed by an acute increase in seawater temperature. These reference genes can possibly be used to normalize target genes in future gene expression studies targeting physiological stress in corals exposed to multiple stressors.

Materials and Methods

Coral collection and exposure to stressor(s)

Coral samples were collected from six randomly chosen colonies of *P. meandrina* at an approximate depth of 5 m from Leleiwi Beach Park in East Hawai`i. Colonies were split up into either of the two treatment tanks or into the control tank. The coral fragments were maintained in 75 L flow-through aerated aquaria set at a constant through flow rate of 7.15 ml s^{-1} and kept at 25˚ C. The tanks were placed under semi-permeable Duraweave material (Cover-all) that transmits light in the solar spectrum from 2500 -300 nm.

The colonies were allowed to acclimatize under the above conditions for a period of 3 weeks (Downs 2005). Then, the corals were placed in treatment tanks (control (C), +2º C sea water temperature (T), and nutrients and +2º C sea water temperature (NT)). Corals in the NT treatment were exposed to a constant addition of 20 μM NH_4 seawater for 32 days before beginning the acute increase in seawater temperature. After the 32 day exposure period to elevated levels of nutrients, both the NT and T treatments were subjected to a temperature increase in seawater over a continuous 48 h period. The water temperature of the aquariums was elevated +2° C to 27° C over a 3 h period and maintained above 27 °C. All treatments (C, T, NT) were sampled at 30 min, 6 h, 24 h, and 48 h after 27° C was reached. One coral fragment from each colony was collected per tank at each sampling time, wrapped in foil, and frozen immediately by immersion in liquid nitrogen. Once the tissue was frozen using liquid nitrogen, samples collected at each time period was stored for RNA analysis by submersion into RNA Later (Ambion), placed at 4° C for 24 h to allow the RNA Later to soak into the tissue, and then stored at -20° C to be used in qRT-PCR.

Selection of candidate reference genes

Five candidate reference genes were selected from the literature to be tested for their expression stability using mRNA from *P. meandrina*. Of the five genes, three had been frequently used as reference genes in gene expression studies of cnidarians primarily from class Anthozoa, and the remaining two were less frequently used reference genes. The three frequently used reference genes were: 18S rRNA, β-actin, and elongation factor (EF1α) (Yanze et al. 1999; Reynolds et al. 2000; Mitchelmore et al. 2002). The less frequently used reference genes examined in this study were senescence associated protein (PS) and Brn1 (Rodriguez-Lanetty et al. 2006; Rodriguez-Lanetty et al. 2007; Mayfield and Gates unpublished).

RNA isolation

Total RNA was isolated from *P. meandrina* using the Totally RNA kit (Ambion) largely following the manufacturer's protocol in an RNAse free environment. A few steps were modified from the protocol to reduce salt carryover from the RNA Later and reduce interference by Trizol found in the RNA

extraction kit. The tissue samples were placed directly on an RNAse free vacuum to remove excess RNA Later liquid then transferred to a sterile Whirl-pak 60 mL plastic sample bag (Nasco). 800 µL of the denaturation solution from the Totally RNA kit was pipetted on top of the coral fragment, and the coral tissue was air blown at 60 psi from the coral skeleton. The tissue slurry was added to a 2.0 mL tube filled with approximately 250 mg of sterile 0.5 mm diameter Zirconia/Silica beads (BioSpec Products) and vigorously shaken (Minibeadbeater-8 Cell Disrupter) for 1 min. The tube containing the tissue slurry was then centrifuged at 12,000 rpm for 2 min at 4 °C. A ¾ v. DEPC-treated water and an equal volume of Phenol:Chloroform:IAA (Promega) solution was added to the lysate and again vigorously vortexed with beads for 1 min. The remainder of the manufacturer's protocol was followed with an overnight precipitation of RNA, followed by a 30 min centrifugation period. The RNA pellet was resuspended with 19.5 µL of DEPC water and 0.5 µL of RNAsin ribonuclease inhibitor (Promega). RNA concentration in the final extracts was measured using the nanodrop ND-1000 Spectrophotometer (Nanodrop Technologies). The RNA was further purified of genomic DNA contamination by DNAse I digestion, according to the manufacturer's protocol (Promega).

Reverse transcription and qPCR

A commercial reverse transcription kit was used according to the manufacturers instructions to reverse transcribe 1 µg of DNAse treated RNA in a 20 µL reaction (iScript cDNA Synthesis Kit, Bio-Rad). DEPC treated water was added to dilute the 20 µL RT reaction products to a final volume of 200 µL. The qPCR assays were performed by using a commercial 2X SYBR-Green master mix buffer (BioRad). qRT-PCR assay efficiency was calculated for each gene using a 6-step, 10-fold cDNA dilution series. Results were documented as cycle threshold values of background subtracted qPCR fluorescence kinetics.

Analysis of results

Relative expression quantities were calculated using the comparative C_T method from qPCR results (Vandesompele et al. 2002). Two gene stability analysis programs, GeNorm (Vandesompele et al. 2002) and NormFinder (Andersen et al. 2004), were used to rank reference genes in order of stability.

The GeNorm method, as previously described by Vandesompele et al. (2002), was used to determine the reference gene expression stability measures ("M-value"). The "M-value" for each gene is calculated as the arithmetic mean of pairwise variation between a particular gene and all other control genes. This program relies on the theory that the expression ratio for ideal internal control genes is identical in all samples, regardless of the experimental condition or treatment. Genes with low M values have the least variation in expression ratios with other genes and are the most stably expressed and vice-versa genes with a high M value have a large variation in the expression ratio are less stably expressed.

The second method of analyzing relative expression stability of candidate reference genes in this study was NormFinder, which has previously been described by Andersen et al. (2004). The relative expression of reference genes were analyzed for stability by NormFinder using GenEx software (Multid Analysis, California). NormFinder generates a gene stability measure using a "model based approach" by separately ranking a set of candidate reference genes according to their expression stability in a given sample set and given experimental design. The mathematical equation estimates the overall expression variation of each candidate reference gene in addition to the variation between sample subgroups of the sample and generates a "stability value" for each that is a direct measure for the estimated expression variation.

Results

Expression of reference genes during exposure to elevated heat and nitrogen levels

The raw expression levels for the five candidate reference genes that were analyzed fell into three categories based on transcript abundance: (1) high transcript abundance (average C_T value below 20): 18S; (2) median transcript abundance (average C_T value 20-25): β-actin, PS; and (3) low transcript abundance (average C_T value <25): EF1-alpha, Brn1.

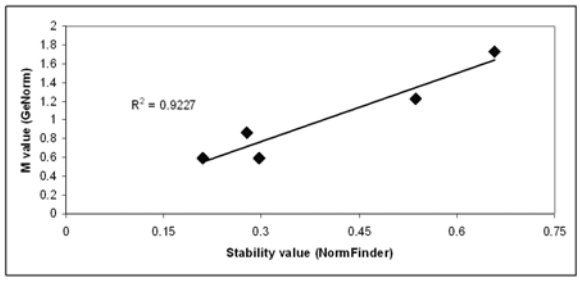

Figure 1: The correlation (R^2=0.9227, P=0.009) of expression values between reference gene ranking programs, M value (GeNorm, Vandesompele et al. 2002) and stability value (NormFinder, Andersen et al. 2004).

Analysis of gene-stability in reference genes

Both gene expression stability programs ranked the RNA targets similarly from most to least stable, with a strong correlation in raw stability values (R^2= 0.9227, P = 0.009) (Fig. 1). Results from both programs showed Brn1 was the most consistently expressed gene

followed by β-actin, and 18S (Fig. 1). Both programs also produced similar results with EF1α and senescence- associated protein (PS) exhibiting the least stable expression (Fig. 1). Because both expression stability programs had similar results, only GeNorm values are interpreted and were further used to analyze expression of *P. meandrina* samples. To ensure that the most stable genes were not co-regulated, each of the highest ranked genes was removed alternately, and gene stability rank was reassessed. No changes in the order of reference gene rank stability were observed. As shown in Fig. 2, the reference genes with the lowest M values and highest expression stability in *P. meandrina* coral tissue were Brn1 and β-actin with M values of 0.2095 and 0.2775 respectively. 18S was the third most stably expressed gene with an M value of 0.2963. These genes were designated to have stable expression because the M<0.4 (Vandesompele et al. 2002).

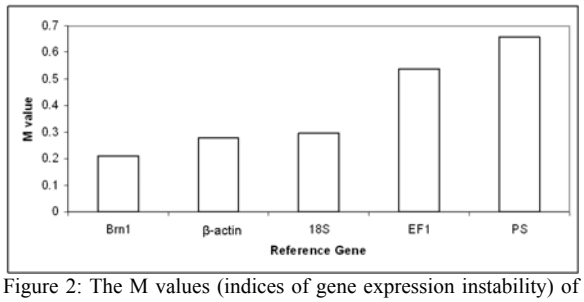

Figure 2: The M values (indices of gene expression instability) of candidate reference genes calculated from GeNorm analysis

Discussion

In this study, we sought suitable reference genes that could be used for future gene expression studies in the reef-building coral *P. meandrina* exposed to long term elevation of nitrogen followed by an acute increase in seawater temperature. Appropriate reference genes are necessary in gene expression studies to normalize sampling differences and identify the true expression differences in an experiment. In cases where no single normalization gene can be found it is best to use multiple genes to normalize data because the variation in multiple genes is less than the variation of a single gene (Andersen et al. 2004).

Several studies have compared different statistical programs to order candidate reference genes and found a similar ranking of stable reference genes within these programs (deBrouwer et al. 2006; Willems et al. 2006; Peltier and Latham 2008). Our study also compared the statistical programs GeNorm and NormFinder and found that candidate genes were ranked similarly by expression stability (Fig. 1).

The study described here shows that reference genes: Brn1, β-actin and 18S, are the most stably expressed in the coral, *P. meandrina*, under a long-term exposure to elevated nitrogen and an acute increase in sea water temperature (Fig. 2). A POU-III (acronym of Pit, Oct, Unc) class gene, Brn1, derived from a common eumetazoan ancestor, is expressed in the geosensory structures of vertebrates, insects and cnidarians (Erkman et al. 1996; Certel et al. 2000; Jacobs and Gates 2001; O'Brien and Degnan, 2002; O'Brien and Degnan 2003). The Brn1 gene is constitutively expressed at low levels in the cell most likely because of its conserved role in sensory cell development (O'Brien and Degnan 2002). The β-actin gene was the second most stably expressed gene in the set of reference genes (Fig. 2) and has been used as a reference gene for multiple cnidarian gene expression studies (Weis and Reynolds 1999; Reynolds et al. 2000; Rodriguez-Lanetty et al. 2007). β-actin encodes a ubiquitous cytoskeletal structural protein and is expressed at moderate levels in the cell. 18S rRNA, is in the small ribosomal subunit in most eukaryotes, and has been considered to be an ideal reference gene because rRNA is less likely to vary than mRNA under the same conditions (Bustin 2000). 18S rRNA as an internal control alone can be limiting because it may not always represent the overall cellular mRNA population (Suzuki et al. 2000). Although 18S ranked behind Brn1 and β-actin, this gene has shown to be constitutively expressed in many studies because rRNA synthesis is independent of mRNA synthesis (Franzellitti et al. 2005; Jorgensen et al. 2006; Tang et al. 2007).

Comparing the results of this study to previous qRT-PCR studies utilizing reference genes demonstrates the increased stability of a "new" reference gene, Brn1, which can possibly be used for stress experiments in reef-building corals alongside more popular reference genes like 18S and β-actin. Together, these reference genes can be used in future studies to normalize gene expression analysis of reef-building corals exposed to nutrient and temperature stressors.

CORAL HEALTH AND DISEASE ASSESSMENT IN THE U.S. PACIFIC TERRITORIES AND AFFILIATED STATES

Bernardo Vargas-Ángel[1], Benjamin Wheeler [2]

[1] Joint Institute for Marine and Atmospheric Research, University of Hawaii, NOAA-PIFSC, Honolulu, HI
[2] Department of Oceanography, University of Hawaii, Honolulu, HI

Abstract. Quantitative coral disease assessments were conducted at 40 different U.S. Pacific coral islands, banks, and atolls, spanning more than 5000 km apart and over a 40° latitudinal gradient Distribution and abundance of disease were determined based on 2, 25-m belt transects (2–6 wide) at 326 sites, and ten broad diseases were identified, affecting 25 scleractinian genera. Pacific-wide, the most geographically and taxonomically widespread diseases were bleaching and skeletal growth anomalies, detected at >65% islands/atolls and on 19 and 11 genera, respectively. Band diseases (black band and banded fungal disease) were rare (<0.1% prevalence), with only two cases enumerated on *Porites* and *Coscinaraea*. Although Pacific-wide mean prevalence was low, site-specific hotspots occurred at Johnston, Kure, and Rose Atolls, French Frigate Shoals, and Guam. Prevalence patterns also varied among coral taxa, with only a few families being disproportionately affected by disease: Poritidae, Acroporidae, and Faviidae. Of potential concern is the presence of white syndrome at Johnston Atoll and French Frigate Shoals which can result in severe and rapid tissue loss, particularly on the tabular *Acropora cytherea*.

Key words: Coral disease, prevalence, U.S.-affiliated Pacific Territories

Introduction

Disease is defined as any impairment that interferes with or modifies the performance of normal physiological functions, including responses to environmental factors, toxicants, and climate; infectious agents; inherent or congenital defects; or a combination of these factors (Wobeser 2006). Pacific-wide, there is growing concern pertaining to the threat of increased prevalence, geographic distribution, and host range of coral diseases, particularly in the Great Barrier Reef (GBR), the Marshall Islands, the Red Sea, the Philippines, East Africa, and the Hawaiian Archipelago (Willis et al. 2004; Aeby 2006; Harvell et al. 2007). NOAA's Coral Reef Ecosystem Division (CRED) has embarked on a long-term, broad-scale coral disease assessment and monitoring program aimed at documenting the distribution and prevalence of coral diseases on U.S. Pacific reefs and investigating the factors that may be contributing to the occurrence of disease. Within this framework, between 2006 and 2007, a total of 326 coral disease surveys were conducted at 5 major regions, including: main Hawaiian Islands, Northwestern Hawaiian Islands, American Samoa, the Pacific Remote Island Areas (PRIA), Guam, and the Commonwealth of the Northern Mariana Islands (CNMI). These surveys are a coordinated effort within NOAA's interdisciplinary, Pacific Reef Assessment and Monitoring Program (RAMP).

Materials and Methods

Disease assessments were conducted along two, haphazardly placed 25-m belt (2–6 m width) transects laid end to end, separated by approximately 5 m. The smaller survey area was implemented at disease-rich sites or where surge, currents, or sea conditions precluded expanded surveys. Within belt transects, all diseased coral colonies were enumerated, identified to genus level, measured in two planar dimensions, and assigned to 1 of 10 lesion categories including: skeletal growth anomalies (SGA), acute tissue loss (hereafter white syndrome; WSY), subacute tissue loss (hereafter tissue loss; TLS), pigmentation response (PRS), trematodiasis (TRE), endolithic fungal infection (EFI), banded fungal infection (BFI), black band disease (BBD), and 'other' (OTH), including algal and cyanophyte infections, and syndromes of unknown etiology (see NOAA 2009 for lesion characterization and description). Colonies exhibiting full, partial or spotty bleaching (BLE) were also tallied and thus, hereafter, bleaching is treated as a disease state. Case counts were complemented with digital photography, as well as tissue collections for future histological examination and verification. A second diver performed community structure surveys by counting and identifying, to the genus level, all colonies within 50–100 cm on both sides of each transect line. Alternatively, at 37 sites in the CNMI, colony counts were conducted using 15–16,

haphazardly placed 0.25 m^2 quadrats. All the above data allowed for the computation of prevalence per genus/disease state, as follows: P = [(total no. cases of a specific disease for the genus × 100) ÷ (colony density of that specific genus per site × total area surveyed for presence of disease)].

Results

A total of 1744 cases of disease were recorded at 67% (220) of the sites surveyed. Farallon de Pajaros in the northern CNMI was the only island where no disease was recorded. A summary of prevalence of disease for each island group and genera are presented in Table 1.

The assessments conducted in American Samoa revealed the highest archipelago-wide mean prevalence (4.3% SE 1.3). Island-specific mean prevalence was the greatest at Rose Atoll (11.7% SE 5.7) and the lowest at Swains Island (1.3% SE 0.8). Of the 62 sites visited, 38 (61%) contained disease, and 7 disease states were enumerated: BLE, SGA, WSY, BBD, PRS, EFI, and OTH. Archipelago-wide, diseases were observed on corals belonging to 14 genera, with *Montastrea*, *Favia*, and *Montipora* exhibiting the greatest percent of cases (30.7%, 34.4%, and 14.8%, respectively), and *Favia*, *Porites*, and *Coscinaraea* showing the greatest mean prevalence values (1.5%, 0.5%, and 0.5%, respectively). Other lesions (OTH), particularly algal/cyanophyte infections were the most numerous disease state, representing 75.3% of cases and notably abundant on 2 west-northwestern forereef sites at Rose Atoll, in the vicinity of a major shipwreck impact site (Schroeder et al. 2008). Island-wide mean prevalence of OTH at Rose amounted to 9.5 (SE 0.5) and affected corals in the genera *Favia*, *Montastrea*, *Porites*, and *Montipora*. In addition, BLE although present at all islands was sporadic and mild, with the highest prevalence values observed at Ofu-Olosega (8.5%); archipelago-wide, however, mean prevalence of BLE amounted only to 0.6% (SE 0.2). BLE occurred mostly on *Porites*, *Montastrea*, and *Montipora*. Lesions involving SGA were occasional, representing 9.4% cases and occurring predominantly around Tutuila and Ofu-Olosega on *Acropora* and *Astreopora*, respectively; archipelago-wide mean prevalence of SGA was 0.8% (SE 0.4). PRS and EFI were also sporadic (6.0% and 7% of cases, respectively), with the greatest island-specific mean prevalence values for Rose Atoll and Tau (1.9% and 3.4%, respectively). Finally, cases of WSY and BBD were rare, representing only 1.7% and 0.2% of total, respectively; archipelago-wide mean prevalence for these two disease states was also low, amounting to 0.06% (SE 0.03) and 0.01% (SE 0.01) respectively.

Of the 64 sites surveyed in the Northwestern Hawaiian Is., 81% contained disease, and 8 different types of lesions were identified: BLE, WSY, TLS, SGA, PRS, TRE, EFI, and OTH; with a region-wide mean prevalence of 3.1 (SE 0.6). Diseases were observed on the 4 main reef-building coral genera (*Porite*s, *Montipora*, *Acropora*, and *Pocillopora*), of which nearly 70% of cases occurred on *Porites*. The greatest number of disease states was recorded at French Frigate Shoals and the lowest at Laysan Island (8 and 2, respectively; Table 1). Mean disease prevalence was greatest at Kure Atoll (7.3% SE 3.7), while Necker Island exhibited the lowest (2.0% SE 1.8). Three disease states, PRS, BLE, and TRE, were the most widespread and abundant. Although BLE was quite common at Laysan and Lisianski, prevalence values were relatively low (1–5%); BLE was moderate and focal and mostly affected on corals of the genera *Porites* and *Montipora*. Lesions involving PRS were ubiquitous but also occurred at low levels of prevalence, not exceeding 3% at any of the sites visited. In addition, the parasitic *Porites* TRE occurred at moderate levels at most sites, except for 2 western backreef sites at Kure Atoll, where prevalence values reached 23–27%. This was the result of reduced numerical abundance of colonies of the host genus at the sites where cases of TRE were enumerated. Together with TRE, lesions involving TLS, BLE, and PRS were present at 7 of the 8 islands/atolls. The 2006 surveys encountered TLS lesions exclusively on colonies of the genus *Porites* and low island-wide mean prevalence values (< 0.5%). Finally, of potential concern are WSY conditions detected on the tabular *Acropora cytherea* only at French Frigate Shoals. Although prevalence values only amounted to 4% for any one site, French Frigate Shoals harbors the largest population of *A. cytherea* in the Hawaiian Archipelago.

For Guam and the CNMI, mean disease prevalence region-wide was relatively low (2.9% SE 0.4), but as in the other archipelagos, exhibited considerable spatial variability. Sixty-six sites at 12 different islands were surveyed in this region and a total of 8 disease states were recorded: BLE, SGA, WSY, TLS, PRS, EFI, BFI, and OTH. The highest island-wide prevalence occurred at Guam (7.3% SE 1.9) and the lowest at Pagan (0.1% SE 0.1). Disease affected the greatest number of scleractinian genera (19) in the Guam-CNMI region: *Porites*, *Astreopora*, and *Cyphastrea* accounted for more than 75% of all cases and exhibited the greatest prevalence. In addition, the 3 main disease states, BLE, EFI, and PRS (in order of prevalence) accounted for more than 65% of cases. Cases of BLE were common particularly around the inhabited Guam, Saipan, Tinian, and Rota and also at uninhabited Alamagan.

Site-specific prevalence of BLE was as high as 12% around Guam. However, mean archipelago-wide prevalence was only 1.3% (SE 0.4). For the most part, BLE was mild to moderate and affected primarily corals in the genus *Astreopora*. EFI cases were widespread and numerous, predominantly around Saipan on the genus *Cyphastrea*, where site-specific prevalence values were as high as 20%; archipelago-wide mean prevalence only reached 0.9% (SE 0.4). Lesions involving PRS on *Porites* occurred mainly at Guam and Tinian, where mean prevalence values amounted to 2.0% and 1.0%, respectively; archipelago-wide, mean prevalence was 0.5% (SE 0.2). Cases of WSY, BFI, TLS, and SGA were sporadic and occurred in low, region-wide mean prevalence (0.1–0.2%).

The 80 sites surveyed in the PRIA revealed a region-wide mean prevalence of 2.8% (SE 0.7), and 6 lesion types (SGA, WSY, TLS, BLE, PRS, OTH) were identified affecting 12 different scleractinian genera, with *Acropora*, *Montipora*, and *Porites* accounting for 92% of cases. Diseases occurred at 43 (54%) of sites surveyed, with SGA being the most geographically and taxonomically widespread disease, detected at nearly 40% of sites. SGA were particularly abundant at Johnston Atoll, where site-specific prevalence was as high as 25.3%. WSY, which was hosted by 4 scleractinian genera, including *Acropora*, *Montipora*, *Goniastrea*, and *Platygyra*, was the second most prevalent disease region-wide (mean prevalence = 0.9%, SE ± 0.1%) with nearly 90% cases occurring at Johnston Atoll. Additionally, PRS and OTH, particularly algal algal/cyanophyte infections and tube-worm infestations, were infrequent and occurred in low prevalences region-wide (range: 0.1 and 0.4%, respectively). Overall, mean prevalence of all diseases was the highest at Johnston Atoll (8.5% SE 2.5) and lowest at Baker Island (0.1% SE 0.1) and patterns of prevalence varied considerably among coral genera with *Acropora*, *Montipora*, and *Porites* being disproportionately affected by SGA and WSY. Of potential concern is WSY, which results in severe and rapid tissue loss, particularly on the tabular *Acropora cytherea* at Johnston Atoll.

Mean, region-wide prevalence amounted to 1.1% (SE 0.3) for the main Hawaiian Islands, where 54 sites were surveyed and 7 disease states enumerated: BLE, SGA, TLS, TRE, EFI, PRS, and OTH. Disease affected 6 coral genera, with *Porites* accounting for more than 90% of the total number of cases (316). Four lesion types, SGA, TLS, EFI, and PRS, were the most widespread and abundant; however, except for limited small areas of higher abundance, disease-specific mean prevalence amounted to less than 2%; All 7 diseases were recorded on corals around the inhabited islands of Hawaii and Maui; Kauai followed with 6 disease states. Limited insight is available for Oahu, as only 1 representative survey was completed in 2006. Kauai exhibited the greatest mean prevalence (3.7% SE 1.8) and, on surrounding reefs, EFI, SGA, and TRE were the most common lesions. The island with the second highest mean prevalence was Lanai (1.5% SE 1.3). This was a result of bleaching occurrence on a few colonies of *Leptastrea*; this genus exhibited overall low numerical abundance at the sites where bleached colonies were encountered. The more remote islands of Niihau and Lehua exhibited both the lowest number of disease states (2) as well as lowest mean prevalences (0.5% SE 0.3 and 0.2% SE 0.1, respectively).

Discussion

This study represents perhaps the most extensive quantitative survey of coral disease across the U.S. Pacific reefs. Surveys detected disease at 67% of sites, and patterns of distribution and abundance varied considerably within and among islands, regions, and coral genera, with only a few taxa being disproportionately targeted by disease. The Northwestern Hawaiian Islands exhibited the greatest percent occurrence of disease with nearly twice as many cases (35%) as any other region; the PRIA exhibited the lowest (9.8%). Additionally, the most numerically abundant disease states Pacific-wide were PRS (20.5%) and BLE (16.1%); and the least abundant, BBD and BFI (0.05% each). However, relative to coral colony density, the most prevalent diseases were BLE and SGA (0.64% and 0.58%, respectively). Pacific-wide, mean prevalence was relatively low (2.8% SE 0.5), with the lowest mean value registered for the main Hawaiian Islands (1.1% SE 0.3) and the highest for American Samoa (4.3% SE 1.3). These archipelago-wide means are lower than those in disease-stricken regions of the Great Barrier Reef and the Caribbean (Puerto Rico, Mexico, and Jamaica; range 6.3–16.6%; Weil 2004; Willis et al. 2004). However, island-specific mean prevalences as high as 7.3%, 8.3%, and 11.7% for Guam, Johnston, and Rose Atoll, respectively, underpin the importance of continued coral disease monitoring to provide warning regarding the potential risk of specific coral populations.

Disease distribution also varied among island groups. For example, the parasitic TRE on *Porites* was only recorded in the Hawaiian Archipelago, while BBD and BFI were exclusive to American Samoa and the CNMI, respectively. The other disease states, BLE, PRS, SGA, WSY, TLS, EFI, and OTH, were more widely distributed among island groups. Additionally, different island groups exhibited differing levels of abundance and prevalence of

specific lesions. For example, BLE conditions were the most prevalent disease state in the Northwestern Hawaiian Islands and Guam-CNMI. Conversely, SGA and WSY were the most prevalent diseases in the PRIA, while OTH was in American Samoa. Factors including, but not limited to pathogen distribution and life history, environmental conditions and disturbances, host abundance, susceptibility, disease transmissibility and virulence may determine the occurrence and prevalence of disease (Wobeser 2006).

The 1744 cases tallied in this study occurred on 25 different coral genera, belonging to 10 scleractinian families. The Poritidae exhibited both the highest frequency of occurrence and mean prevalence in the main Hawaiian Islands (90.1% of cases, mean prevalence = 0.6%) and the Northwestern Hawaiian Islands (69.8% of cases, mean prevalence = 2.4%, respectively). Within the Poritidae, TRE and PRS were the most numerically abundant diseases (60% of cases, combined), while BFI and WSY were the only two syndromes not observed on this taxon. Comparatively, the Acroporidae was the taxon most susceptible to disease in the PRIA (65% of cases, mean prevalence = 1.3%) and the Faviidae in American Samoa (58.2% of cases, mean prevalence = 2.2%). Pacific-wide, SGA and WSY were the most numerically abundant and prevalent diseases on the Acroporidae (52% and 0.6%, respectively), while OTH (particularly algal/cyanophyte infections) were the most numerically abundant and prevalent lesions on the Faviidae (62% and 0.7%, respectively).

Overall, the three major families, Poritidae, Acroporidae, and Faviidae, hosted the greatest number of disease states (8, 6, and 6, respectively), as well as the greatest levels of mean prevalence (1.0%, 0.9%, and 0.7%, respectively). Pacific-wide, these three families are amongst the most numerically abundant and diverse taxa, representing a key community structural component. For example, these 3 families accounted for 70–80% of the live coral cover and 65–85% of colonies on the study reefs in American Samoa, the PRIA, and Guam-CNMI. Similarly, in the Hawaiian Archipelago, *Porites* alone represents more than 60% of the live coral cover and more than 47% of colonies (Vargas-Ángel and Kenyon unpubl. data). Recent studies indicate an escalating number of diseases and prevalence levels affecting a selected number of scleractinian taxa, whereby *Acropora*, *Montastraea*, and *Colpophyllia* appear highly susceptible to disease on Caribbean reefs, while *Porites*, *Acropora*, *Montipora* and *Pocillopora* are the chief disease-hosting genera on Indo-Pacific reefs (Weil 2004; Willis et al. 2004; Aeby 2006; Harvell et al. 2007). To what extent host susceptibility to disease is determined by numerical abundance and/or a life history trait is an important topic for further scientific investigation.

This study represents the first comprehensive attempt at assessing the distribution and abundance of coral diseases in the U.S.-affiliated Pacific States and Territories. Although archipelago-wide mean prevalences are relatively low (1.1–4.3%; Table 1), site-specific hotspots occur at Johnston, Kure, and Rose Atolls, French Frigate Shoals, and Guam. In addition, the scleractinian families Poritidae, Acroporidae, and Faviidae appear to be disproportionately affected by disease. Potential outbreaks of host-specific diseases can be a source of concern, given that these families are key contributors to reef building and structural dynamics in many U.S. Pacific reefs. Periodic regional monitoring, coupled with continued targeted research, will allow a better understanding of the natural coral disease dynamics and, therefore, help managers formulate informed decisions regarding the potential risk of specific coral populations.

Acknowledgements

NOAA Coral Reef Conservation Program for financial support. White band syndromes in *Acropora cervicornis* off Broward County, Florida: Transmissibility and rates of skeletal extension and tissue loss

A.J. Smith[1], J.D. Thomas[1]

1) Nova Southeastern University, Oceanographic Center, 8000 N. Ocean Drive, Dania Beach, FL 33004

Abstract. The high latitude thickets of *Acropora cervicornis* off Broward County flourish despite the presence of natural and anthropogenic impacts. These populations provide a unique study opportunity which stands out against the disease stricken areas of the Florida Keys. This study uses time sequenced photographs to examine how *A. cervicornis* is coping with white band syndrome stressors. Variables monitored include healthy colony skeletal extension rates, diseased colony skeletal extension rates, and tissue loss. The transmissibility of the white band syndromes was examined through tissue grafting experiments. Skeletal extension rates of healthy and diseased fragments averaged 0.94 ± 0.4 cm mo^{-1} and 0.79 ± 0.4 cm mo^{-1} respectively. Mean linear tissue loss from disease signs was 1.2 ± 2.5 mm d^{-1} or 3.7 ± 7.5 cm mo^{-1}. In transmission experiments, 72.5% of all trials involving direct tissue contact resulted in low or no disease sign transmission. *A. cervicornis* thickets in Broward County are growing similar to other studies in Florida but faster than other areas of the Western Atlantic while tissue loss from disease is lower. White band syndromes are always present in Broward County, but the low prevalence and transmission of the syndrome seems to limit its affect on the thickets.

Key words: White band disease, *Acropora cervicornis*, growth rates, tissue loss, disease transmission

Introduction

Surveys in Broward County, FL have discovered several thickets of *Acropora cervicornis* (Thomas et al. 2000, Vargas-Angel et al. 2003). Despite the presence of abundant natural and anthropogenic impacts, the *A. cervicornis* thickets are exceptionally healthy. These thickets provide a unique site for studying white band syndrome effects on acroporid populations when compared to the disease-stricken populations of the majority of the Caribbean including the Florida Keys National Marine Sanctuary (Vargas-Angel et al. 2003).

Recent observation of *A. cervicornis* populations directly off Fort Lauderdale, Lauderdale-By-The-Sea, and Pompano beaches in Broward County and other locations have shown that white band disease seems more complex than previously believed. For this reason the term white band syndromes is being used to include all cases. Three patterns of tissue loss have been observed during this study. The first is a fast moving, clearly defined white band of tissue necrosis next to 3-7 cm of denuded skeleton followed by algal successional stages. The second is similar to the first but it is a slower moving, well defined white band of denuded skeleton, followed by no more than 1-2 cm of denuded skeleton, then algae. Both of these tissue loss patterns resemble previously described patterns referred to as white band Type I (Gladfelter 1982, Peters 1984). White band type II has been reported in the Bahamas with an area of bleached tissue preceding the necrotic tissue (Ritchie and Smith 1998). White band type II was not seen during this study. The third observed tissue loss pattern looks similar to White Pox observed on *Acropora palmata*. This condition has irregular areas of denuded skeleton, termed 'patchy necrosis,' which spreads rapidly, regularly killing large portions of colonies. Similar patterns of rapid tissue loss were reported around the time when the first observations of white band disease occurred (Bak and Criens 1981). *Serratia marcescens* has been found to be a cause of similar looking patchy necrosis in *A. palmata* (Patterson et al. 2002). Williams and Miller discuss similar tissue loss patterns in their study at White Bank off Key Largo and refer to it as 'rapid tissue loss' (Williams and Miller 2005). It is still unclear if or how this rapid tissue loss is linked to the white band diseases. The presence of both in Broward's *A. cervicornis* thickets provides a unique opportunity for study.

Many studies including Atlantic and Gulf Rapid Reef Assessment surveys show that disease continues to be a considerable stressor on acroporid populations in the western Atlantic (Lang 2003, Sutherland et al. 2004, Weil 2004, Weil et al. 2006). Disease, low sexual recruitment, and anthropogenic impacts are to cause for the Caribbean acroporid corals to be listed

as threatened on the Endangered Species Act (Anonymous 2005, Hogarth 2006) and listed as critically endangered under the International Union for the Conservation of Nature (IUCN) Red List criteria (Carpenter et al. 2008). This project was developed as part of a larger project investigating *A. cervicornis* thickets off Broward County, Florida for comparison to other western Atlantic acroporid populations. The primary goals of this project were to ascertain 1) healthy and diseased colony growth rates recorded in terms of linear skeletal extension not only for comparison to other populations but also to determine if there was a colony-wide influence from white band syndromes, 2) rates of tissue loss caused by white band syndromes recorded in terms of linear tissue loss, and 3) incidence of disease sign transmission from in-situ tissue grafting experiments confirmed via visual inspection.

Material and Methods

1) Skeletal Extension Rates – Colonies of *A. cervicornis* demonstrating no signs of white band syndromes and those with disease signs were identified for monitoring. On those colonies, branches with healthy tissue were marked 5-7 cm below the axial polyp with cable tied tags. Measurements from cable tie to branch tip were determined through photos calibrated with Coral Point Count with Excel extensions (CPCe) using the ruler photographed next to the branch (Kohler and Gill, 2006). All experiments were conducted at two different thickets concurrently from July through September 2007 and November 2007 through February 2008. Each site had 10 healthy and 10 diseased colonies tagged giving a total of 40 healthy fragments monitored and 40 diseased fragments monitored.

2) Tissue Loss Rates – Cable ties were placed near the tissue/skeleton interface on diseased colonies and used as a baseline from which progression of the disease front could be measured using CPCe in the same method described above. Linear movement of the tissue/skeleton interface was measured by calculating the difference between the cable tie and live tissue between measurements. This was monitored with the same method as above totaling 40 fragments.

To establish that the calibrated photo method is comparable to using calipers in-situ and an acceptable method for determining measurements, a small test was conducted. Five branches of *A. cervicornis* were tagged as they were in the experiment. Measurements were calculated using both methods. Caliper measurements were taken five times rotating around the axis of the branch. Photos were taken from five different angles. A two-sample paired t-Test was used to compare the two methods for each branch measured.

3) Transmissibility – Transmission of white band syndrome signs was observed with direct tissue contact via grafting experiments. There were four different trials 1) a diseased branch with a portion of an active lesion attached to a healthy colony, 2) a healthy branch attached to an active lesion on a diseased colony, 3) a healthy branch from a colony exhibiting disease signs attached to a healthy colony, and 4) a healthy branch from a healthy colony attached to a healthy colony. Branches were simply attached with cable tied tags and observed for disease sign transmission. Ten branches were used for each trial at each site giving a total of 160 fragments. Transmissibility was monitored through observation and photos. Each photographed tissue graft was assigned a classification based on the extent of transmission. The possibilities of transmission are outlined below (Fig. 1).

Classification	Explanation
None	No observed change in tissue color, integrity, or mucus output and no tissue loss on the 'healthy branch'.
Low	Margin of tissue contact showing whitening and possibly some tissue necrosis.
Moderate	'Healthy branch' clearly exhibiting tissue necrosis along grafting boundary.
Severe	Considerable tissue loss due to necrosis and most likely mortality of the transplanted fragment and host portion of the colony.

Figure 1: Chart outlining the four possible outcomes of a transmissibility experiment.

The following photos (Fig. 2-5) are examples of the possible transmission classifications.

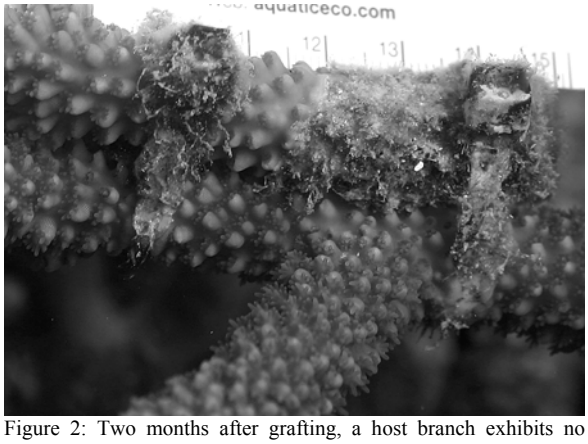

Figure 2: Two months after grafting, a host branch exhibits no transmission while the white band on the transplanted branch has ceased moving and the exposed skeleton was colonized by algae.

Figure 3: Nine days after grafting, a host branch exhibits low transmission while the transplant still has some healthy tissue.

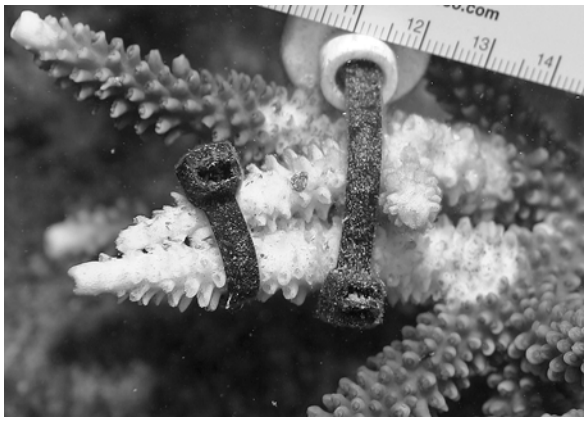

Figure 4: Nine days after grafting, a host branch is demonstrating moderate transmission while the transplant has lost almost all tissue.

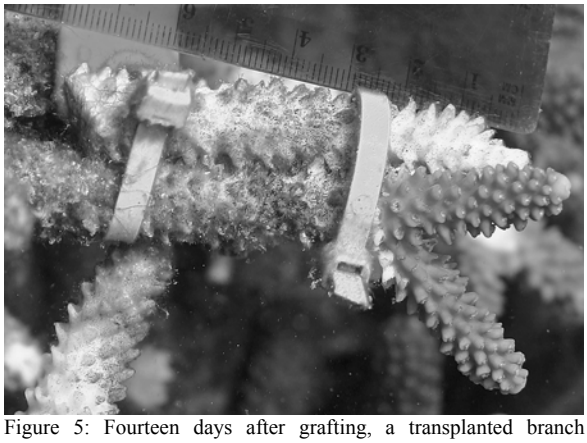

Figure 5: Fourteen days after grafting, a transplanted branch demonstrating severe transmission with no live tissue and the host branch is left with a small amount of tissue on the tip.

Results

The following chart (Fig. 6) lists the rates of healthy and diseased skeletal extension and tissue loss recorded during this experiment.

Measurement	Calculated Means
Healthy Skeletal Extension Rates	0.94 ± 0.4 cm mo^{-1}.
Diseased Skeletal Extension Rates	0.79 ± 0.4 cm mo^{-1}
Diseased Tissue Loss (linear)	1.2 ± 2.5 mm d^{-1} or 3.7 ± 7.5 cm mo^{-1}

Figure 6: Measurements reported as (mean ± SD).

A two sample paired t-test to compare healthy and diseased colony growth rates was conducted, with $\alpha=0.05$, $p=0.37$. This leads to the conclusion that there is no difference between the two skeletal extension rate means.

The comparison of five calibrated photos and five caliper measurements each of five different branches was analyzed using a paired t-test for sample means. With $\alpha=0.05$, the resulting p-values were 0.98, 0.82, 0.31, 0.61, and 0.64. All tests conclude that there is no difference between the two measurement means.

The following charts (Fig. 7-10) list the classifications of tissue grafting experiments in terms of percentage at each location at the termination of each experiment. The summer run was July through September. The winter run was November through February.

Diseased X Healthy				
Classification:	None	Low	Moderate	Severe
Scooter (S)	70%	10%	0%	20%
Oakland (S)	10%	0%	0%	90%
Scooter (W)	30%	10%	30%	30%
Oakland (W)	30%	60%	10%	0%

Figure 7: Transmission classifications for diseased branches attached to a healthy colony host. (S) = Summer (W) = Winter.

Healthy X Diseased				
Classification:	None	Low	Moderate	Severe
Scooter (S)	10%	0%	10%	80%
Oakland (S)	0%	0%	0%	100%
Scooter (W)	0%	10%	30%	60%
Oakland (W)	30%	20%	10%	40%

Figure 8: Transmission classifications for healthy branches attached to a diseased colony host.

Healthy from Diseased X Healthy				
Classification:	None	Low	Moderate	Severe
Scooter (S)	90%	10%	0%	0%
Oakland (S)	100%	0%	0%	0%
Scooter (W)	100%	0%	0%	0%
Oakland (W)	90%	0%	10%	0%

Figure 9: Transmission classifications for a healthy branch from a colony exhibiting disease signs attached to a healthy colony host.

Healthy from Healthy X Healthy				
Classification:	None	Low	Moderate	Severe

Discussion

The table below (Fig. 11) lists annual growth rates of *A. cervicornis* recorded in several locations in the western Atlantic.

Growth Rate (cm y^{-1})	Location	Source
4	Dry Tortugas	(Vaughn 1915)
10.9	Key Largo, FL	(Shinn 1966)
11.5	Eastern Sambo, FL	(Japp 1974)
10	Key Largo, Florida	(Shinn 1976)
7.1	U.S. Virgin Islands	(Gladfelter et al. 1978)
3 to 4	Exuma, Bahamas	(Becker and Miller 2001)

Figure 11: Adapted from Atlantic Acropora Status Review (*Acropora* Biological Review Team 2005).

After converting this study's skeletal extension rates, healthy colonies have an average growth rate of 11.3 cm yr^{-1} and diseased colonies have an average growth rate of 9.5 cm yr^{-1}. These rates are within the same range of other Floridian *A. cervicornis* populations. Analyzing the data with a two sample paired t-test concludes that there is no statistically significant difference between the skeletal extension rate means of healthy or diseased colonies. This demonstrates that white band syndromes only impact the health of the coral at the location of the lesions and does not affect the rest of the colony's growth.

Not many studies have reported disease progression in terms of linear tissue loss. Williams and Miller (2005) discuss patterns of tissue loss similar to those observed in this study. This method of tissue loss termed 'rapid tissue loss' was seen during the study however, every effort was made to select corals that did not demonstrate rapid tissue loss. Corals that exhibited tissue loss patterns conforming to previous descriptions of white band syndrome type I were selected for this study. This study found mean tissue loss to be 0.12 ± 0.25 cm d^{-1}. Williams and Miller observed rates of 4 cm d^{-1} (Williams and Miller 2005) while other studies reported maximum rates of 2 cm d^{-1} (Antonius 1981, Gladfelter 1982, Peters et al. 1983). It seems that other factors must play a role in tissue loss rates such as temperature, season, nutrients, feeding scars, and recent branch breakage.

Transmission experiments involved four different tests. When a diseased branch was attached to a healthy colony the results were mixed. One site had 90% severe transmission. This ended up being an odd response. In all other treatments, the majority of transmission was not severe. It appears that some colonies may have the ability to resist transmission of the disease. Certain genotypes have been proven to be resistant to white band syndromes (Vollmer and Kline 2008). However, since there was some transmission, it appears there must be some sort of tranfer of causative agent or pathogen.

When a small piece of a healthy branch was attached to the lesion of a diseased colony the results were consistent. The majority of the transplants had severe transmission. There were some branches that did not transfer the disease signs (10% in the summer at one site and 30% in the winter at the other site). This supports studies that have shown that injuries such as a feeding scar from corallivorous snails or a fireworm (*Hermodice carunculata*) or in this case branch breakage can be a precursor to disease (Williams and Miller 2005, Sussman et al. 2003).

When a healthy branch from a diseased colony was transplanted to a healthy host the results were consistent. 90-100% of the trials showed no transmission of disease signs. This implies that a pathogen or causative agent is most likely present on healthy portions of a colony but are more concentrated on areas of active tissue loss caused by the white band syndromes.

When a healthy branch from a healthy colony was transplanted to a healthy colony the results were consistent. 100% no transmission was observed in all trials except one which had 20% severe. This further supports the idea from the previous paragraph that a causative agent is present on healthy portions of the colony.

During the transmission experiments, despite the effort to choose only those branches exhibiting disease signs resembling white band disease type I, when a transmission experiment lead to a transfer of disease signs, some branches demonstrated disease signs of white band type I and others the rapid tissue loss discussed earlier. Although each transmission experiment had differing results, 72.5% of all the tissue grafts had low or no transfer of disease signs.

When comparing methods using calipers or calibrated photos for measuring a branch of *A. cervicornis*, all paired t-tests for sample means resulted in p-values that conclude there is no statistically significant difference in the two methods means. The photo method was chosen to be less invasive. The only contact with the coral is the installation of the tag. If the tag is connected firmly with a cable tie gun, it will prevent tag movement and tissue irritation, the fragments can still thrive. Several tagged fragments started to overgrow their tags in just a few months.

In summary, the skeletal extension rates in Broward County are similar to previously recorded rates in Florida. These rates however, seem to be significantly higher than other areas of the western Atlantic. Tissue loss rates due to white band syndromes are faster than corals are growing but less than previously reported rates from the Florida Keys and other locations.

Transmissibility of white band syndromes appears to be more severe when involving small fragments but transmission is not always severe, supporting studies that have shown that tissue damage can be a precursor to disease. A significant portion of tissue grafts did not demonstrate disease signs transfer when directly attached to a diseased colony supporting other findings that colonies can be resistant. Future research such as genotyping of Broward's thickets could prove interesting regarding colony resistance. Using the calibrated photo method will allow future studies to make consecutive measurements with minimal interference with the normal growth and health of *A. cervicornis* colonies. When compared to other western Atlantic populations this study demonstrates that the *A. cervicornis* thickets in Broward County are healthy and growing faster. Despite the constant presence of white band syndromes, the low incidence and low transmission of disease signs seems to play a significant role in the good health of these populations. There is still much to be understood of the white band syndromes and the thickets of Broward County provide an excellent study site for such research.

Acknowledgement

Thank you to Dr. Kiho Kim, Dr. Drew Harvell, and Dr.Cathie Page for allowing me to present this research at the 11th ICRS. It was a great opportunity. Thank you to my advisors Dr. Jim Thomas, Dr. Esther Peters, Dr. Bernardo Vargas-Angel, and Dr. Pat Blackwelder for their time and patience to see this project through to the end. Thanks to all my volunteers: Erin Hodel, Joe Penta, Jen Hester, Dave Portnoy, Kate Koontz, Mike Lehman, and Liam Murphy. I couldn't have done it without you offering your time. Thanks to Kyle Miller and Lisa Gregg for all their help in obtaining the proper permits for this study (SAL 07SRP-606). Also, thanks to Lance Robinson, Dr. Dave Gilliam, and Dr. Dick Dodge for helping facilitate this project.

Abstract. Dark Spot Syndrome (DSS) typically manifests in scleractinian corals as lesions of varying color, size, shape and location that can result in skeletal changes and tissue death. A causative agent for DSS has not yet been identified. The objective of this study was histological and ultrastructural comparison of the cellular and skeletal characteristics of DSS-affected and healthy *Siderastrea siderea* and *Agaricia agaricites*. The greater resolution possible with transmission electron microscopy (TEM) revealed microbial activity and tissue changes not resolvable utilizing histology. DSS-affected tissue had less integrity, with increasing cellular degradation and vacuolization. A high concentration of electron dense inclusions, which appear to be zymogen granules, was concentrated in the calicodermis and adjacent gastrodermal layer. Numerous endolithic fungal cells were observed directly adjacent to the calicodermis in DSS-affected *S. siderea*. Numerous unidentified endolithic cells were observed directly adjacent to the calicodermis in DSS-affected *A. agaricites*. These observations suggest that the coral may be using a digestive enzyme as a defensive mechanism against endolithic cellular invasion.

Key words: Dark Spot Syndrome, *Siderastrea siderea*, *Agaricia agaricites*, ultrastructure, TEM.

Introduction

A significant increase in the incidence and prevalence of coral diseases and the number of species affected has been observed worldwide and likely plays a major role in the decline of reef-building species (Rosenberg & Loya 2004). Most coral diseases are not well characterized, and effects of these diseases on corals at the cellular level have yet to be fully elucidated. Thus, the use of multiple approaches, including molecular, ultrastructural and histological techniques is needed in the investigation of coral disease and pathology.

Siderastrea siderea is an important scleractinian reef-building coral, commonly found throughout south Florida and the Caribbean. Of the several species of Caribbean corals affected by Dark Spot Syndrome (DSS), *S. siderea* is most frequently affected (Gil-Agudelo et al. 2004, Weil 2004, Borger 2005, Gochfeld et al. 2006). DSS typically manifests as black, brown or purple lesions of varying size and shape that can occur across the coral colony surface and at colony edges. DSS does not always cause tissue death; the lesions may disappear without any evident damage, or they can resolve and reappear on a different area of the colony (Gochfeld et al. 2006). If lesions are persistent, development of a depression in the skeleton or tissue necrosis is possible. Even if there is no tissue loss, underlying skeletal changes may occur. These changes may include a permanent dark skeletal discoloration that is observable in longitudinal skeletal slabs (Renegar pers obs.). To date, the cause of DSS has yet to be identified.

Unlike *S. siderea*, which is affected by DSS throughout its range, *Agaricia agaricites* appears to be affected by DSS in certain locations (e.g., Colombia: Garzón-Ferreira et al. 2001; Cayman Islands: Coelho & Manfrino 2007), but not others (e.g., Bahamas: Gochfeld, pers. obs.). DSS in *A. agaricites* typically manifests as much darker brown or black patches than on *S. siderea*. It is not yet known whether DSS found on these species has a common cause or similar impacts at the cellular level. The objective of this study was to use a combination of ultrastructural and histological techniques to describe cellular characteristics and possible pathogenic microbes in DSS-affected and healthy *S. siderea* and *A. agaricites*.

Materials and Methods

Tissue samples of *S. siderea* were collected from 10 healthy and 9 diseased colonies at Lee Stocking Island, Bahamas in July 2006, and from 2 healthy and

6 diseased colonies at Little Cayman, Cayman Islands in June 2007. Samples of 4 healthy and 4 diseased colonies of *A. agaricites* were collected from Little Cayman in June 2007. Examination of the *S. siderea* samples did not indicate substantial differences among locations or years. A fragment of each healthy colony and two fragments of each diseased colony (healthy and DSS-affected tissues) were fixed in glutaraldehyde fixative solution [2 mL 70% glutaraldehyde in 68 mL cacodylic buffer (2.16 g cacodylic acid in 200 mL of 0.22 µm filtered seawater)] in the field. Samples were maintained at 4°C in the fixative for 4-6 days, then divided into three subsets: two for TEM (calcified and decalcified) and one for histological analysis.

For TEM analysis, pieces of tissue approximately 2 mm^2 in size were removed from each fixed colony and post-fixed in buffered 1% osmium tetroxide solution (5 mL 4% aqueous osmium tetroxide in 30 mL of cacodylic buffer) for 1 hour. Samples were then rinsed in buffer, and the sample subset to be decalcified was placed in a diluted decalcification solution (0.032 g potassium sodium tartrate, 0.56 g sodium tartrate, 2.8 g EDTA, 400 mL 12 N HCl in 33.6 L dH_2O). The solution was changed frequently (every 1-2 hours) until each sample was completely decalcified. Samples were dehydrated in a graded series of ethanols, embedded in Spurr resin, and ultrathin sections were cut (40 to 60 nm thick) using a Sorval MT-2 ultramicrotome fitted with a diamond knife. Sections were retrieved on nitrocellulose and carbon coated 200 mesh copper grids, stained with Reynolds lead citrate and/or 2% uranyl acetate solution, and viewed in a Phillips 300 TEM. Electron dispersive spectroscopy (EDS) was used to evaluate elemental composition. Histological samples were decalcified in a 5% HCl/EDTA solution, dehydrated and embedded in Paraplast®, sectioned at 4 µm, and stained with Movat's Modified Pentachrome or Hematoxylin & Eosin.

As mucocyte size has been demonstrated to increase under stress, (Vargas-Ańgel et al. 2007), a quantitative comparison of mucocyte size in *S. siderea* was made from sections that were 500 µm from the aboral interface in 7 healthy and 4 DSS-affected colonies from the Bahamas. The length and width of mucocytes were determined in 5 random fields of view from each section (1000X magnification). Healthy tissue on DSS-affected colonies was taken from at least 1 cm away from DSS-affected tissue. Paired t-tests were used to compare mean cell sizes between healthy and DSS-affected tissues on affected colonies, and unpaired t-tests were used for comparisons between healthy colonies and both types of tissue on affected colonies.

Results

***Siderastrea siderea*.** Healthy corals demonstrated an organized cellular configuration indicative of tissue integrity (Fig. 1A), whereas the DSS-affected tissue exhibited cellular degradation, vacuolization, and necrosis (Fig. 1B). Healthy tissue adjacent to affected tissue on DSS-affected colonies was comparable to tissue on healthy colonies. In healthy calcified tissue, normal aragonite crystals were observed directly adjacent to the calicodermis, and organic matrix was present in decalcified tissue (Fig. 1A). In contrast, aragonite crystals appeared smaller and irregular in calcified tissue from DSS-affected samples, with little organic matrix present in affected decalcified tissue. Numerous zooxanthellae in various stages of cell division were present in the healthy tissue. In DSS-affected corals, there was an apparent decrease in zooxanthellae number, and many appeared abnormal or necrotic, with internal organelle disruption and debris (Fig. 1B).

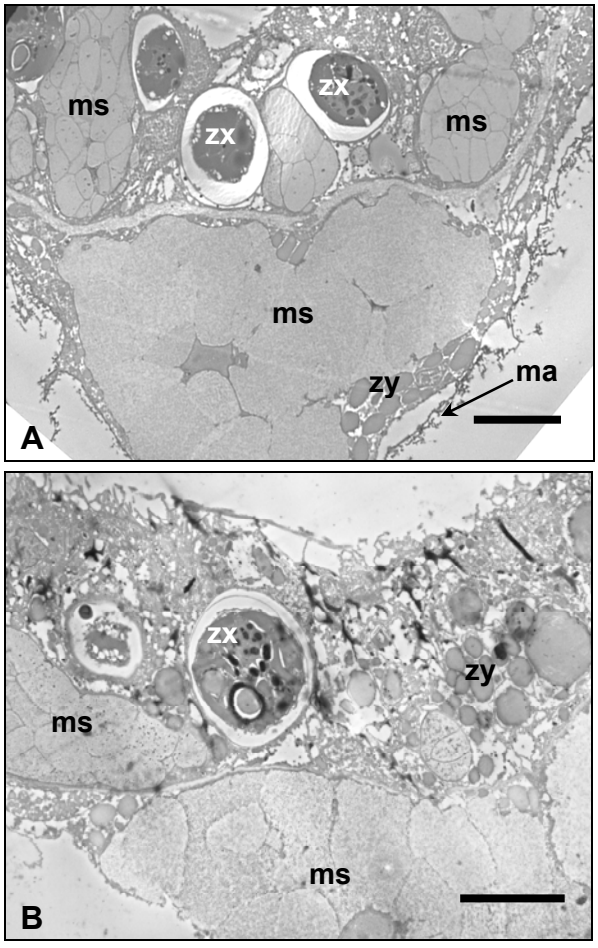

Figure 1. *Siderastrea siderea*, TEM micrographs. A) Healthy gastrodermis; B) DSS-affected gastrodermis. ma: organic matrix; ms: mucocyte; zx: zooxanthellae; zy: zymogen granules. Scale bars: A and B = 10 µm.

In all of the DSS-affected corals, numerous endolithic fungal cells were observed in close proximity to the calicodermis (Figs. 2A & 2B). These fungal cells were associated with swollen, vacuolated mucocytes and an increased concentration of acidophilic/eosinophilic, proteinaceous, electron-dense granules in the calicodermis (Fig. 2A). The morphology and staining properties indicate that these granules are zymogen granules (E. Peters pers. comm., Goldberg 2002). Fungal cells in close proximity to the tissue were not observed in any of the healthy colonies or the samples of healthy tissue from the DSS-affected colonies. Identification and characterization of these fungal cells are ongoing.

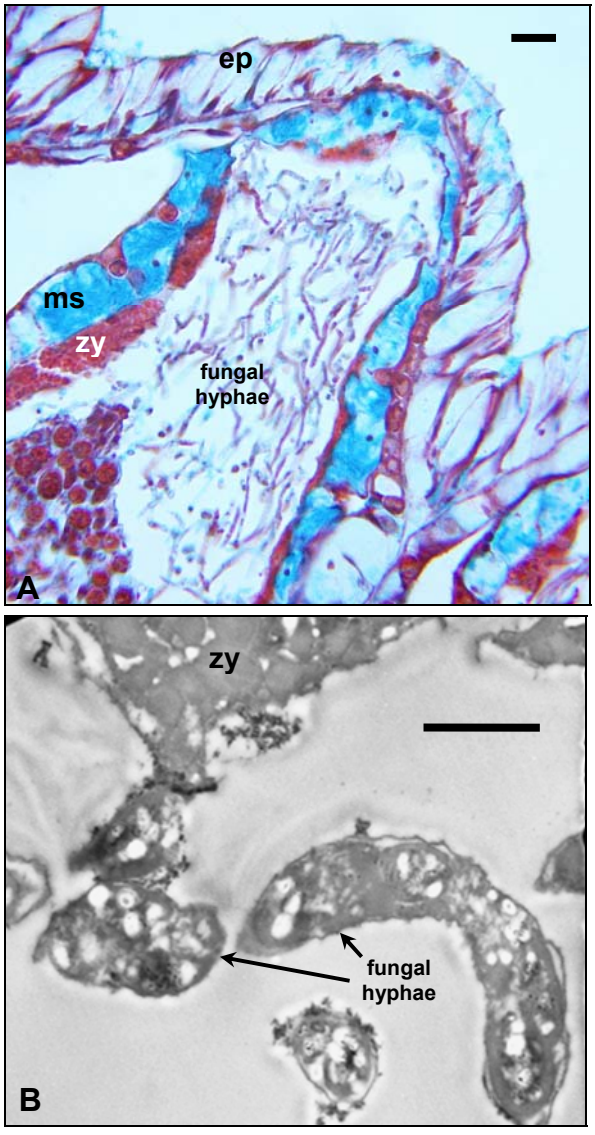

Figure 2. *Siderastrea siderea*. A) Histological micrograph, DSS-affected coral and endolithic fungi; B) TEM micrograph, decalcified DSS-affected coral tissue and fungal cells. ep: epidermis; ms: mucocyte; zy: zymogen granules. Scale bars: A = 20 µm and B = 3 µm

Mucocytes were significantly larger in DSS-affected tissues than in healthy tissues on either healthy (unpaired t=-4.78, df=9, P=0.001) or affected colonies (paired t=3.3, df=3, P=0.046; Table 1). There was no significant difference in the size of mucocytes between healthy tissues on healthy or affected colonies (unpaired t=0.23, df=9, P=0.82).

Table 1. *Siderastrea siderea.* Size of mucocytes (μm^2) in healthy colonies and healthy and DSS-affected tissue on affected colonies.

Tissue type	Mucocyte size (n = cells/colony)
Healthy coral (n=7)	10.3 ± 1.3 (94-236)
DSS-affected (n=4)	26.6 ± 4.1 (62-132)
Healthy tissue on DSS-affected coral (n=4)	9.8 ± 1.5 (150-190)

Agaricia agaricites. Healthy colonies of *A. agaricites* also demonstrated normal cellular configuration (Fig. 3A). The DSS-affected tissue exhibited moderate cellular degradation and vacuolization, particularly of the calicodermis (Fig. 3B). Healthy tissue adjacent to affected tissue on DSS-affected colonies was similar to tissue on healthy colonies. Organic matrix was evident in healthy decalcified tissue. Little organic matrix was present in the DSS-affected decalcified tissue, and aragonite crystals appeared irregular in the affected calcified tissue.

As in *S. siderea*, the most notable difference between affected and healthy tissue in *A. agaricites* was the accumulation of acidophilic electron dense zymogen cells and dispersed granules in the calicodermis and adjacent gastrodermis of DSS-affected tissue (Fig. 3B). Zooxanthellae density appeared to be similar between healthy and affected tissue, and zooxanthellae were observed in various stages of cell division in all of the samples. Zooxanthellae in healthy corals appeared to have a moderately greater intracellular accumulation of starch compared to zooxanthellae in affected corals. This may indicate greater energy demands placed on the zooxanthellae by the coral host in affected corals.

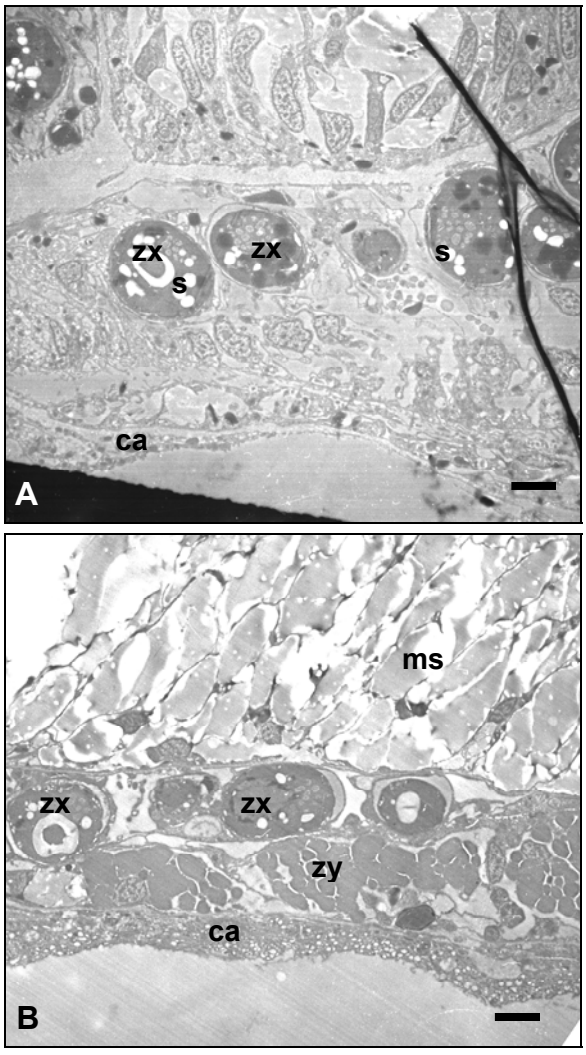

Figure 3. *Agaricia agaricites*. TEM micrographs. A) Decalcified healthy gastrodermis and calicodermis; B) decalcified DSS-affected gastrodermis and calicodermis. ca: calicodermis; ms: mucocyte; s: starch; zx: zooxanthellae; zy: zymogen granules. Scale bars: A and B = 5 µm.

In all of the DSS-affected tissues, numerous protein-staining, unciliated cells were present in close proximity to the calicodermis (Fig. 4). These cells were not observed in any of the healthy corals or in the healthy tissues on DSS-affected colonies. These cells have not yet been identified, although assessment of spatial relationships as well as identification and characterization of these cells is ongoing using fluorescent in-situ hybridization.

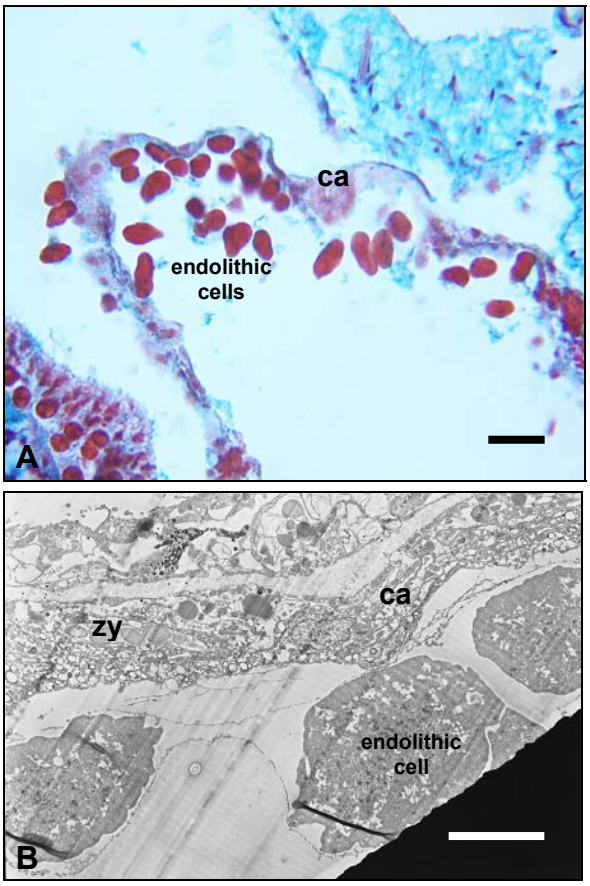

Figure 4. *Agaricia agaricites*. A) Histological micrograph, DSS-affected coral and endolithic cells; B) TEM micrograph, decalcified DSS-affected coral and endolithic cells ca: calicodermis; zy: zymogen granules. Scale bars: A = 20 µm and B = 10 µm.

Discussion

Dark Spot Syndrome causes cellular degradation, vacuolization, and necrosis in affected tissues of *S. siderea* and *A. agaricites*. A concomitant decrease in organic matrix suggests cessation of calcification in affected areas.

An increase in the concentration of proteinaceous, electron-dense inclusions was observed in the calicodermis by histological (Miller et al. 2006) and ultrastructural analysis. The morphology and staining properties indicate that these are zymogen granules. Zymogen granules are normally observed within secretory epithelial cells (granular gland cells), and are reported to function as an aid in feeding. The granules can be released into the gastrovascular cavity for extracellular digestion (Galloway et al. 2007, Goldberg 2002). In the DSS-affected tissues, large zymogen cells were observed in the calicodermis and zymogen granules were often observed free within the calicodermis and adjacent gastrodermis. Galloway et al. (2007) also observed dispersed acidophilic granules associated with endolithic mycosis.

Numerous endolithic fungal cells were observed directly adjacent to the calicodermis in DSS-affected *S. siderea*. Fungal hyphae have recently been observed in association with DSS lesions in several species of Pacific corals (Work et al. 2008) and in *S. siderea* from Florida and Puerto Rico (Galloway et al. 2007). Fungal endoliths are well known from corals and may be pathogenic to their hosts (Le Campion-Alsumard et al. 1995, Bentis et al. 2000, McClanahan et al. 2004). In gorgonians, the fungus *Aspergillus sydowii* causes the disease Aspergillosis, which causes purpling and necrosis of the gorgonian tissue (Smith & Weil 2004). The fungal cells in *S. siderea* are morphologically consistent with the genus *Aspergillus* (Moore et al. 2003); however, their identity has not yet been ascertained.

In contrast, DSS-affected tissues of *A. agaricites* did not contain fungal hyphae. However, a large number of unidentified endolithic cells were observed directly adjacent to the calicodermis. Thus, although DSS-affected tissues in both species exhibit tissue degradation and increased zymogen concentration, the difference in the type of endolithic cells present suggests that the causal agent of DSS in these two coral species may be different. In fact, Weil (2004) suggests that there may be multiple types of DSS (=DSD), and our observations, in concert with differences in zooxanthellar responses in two DSS-affected species (Cervino et al. 2001), suggest that DSS may represent a suite of different conditions.

The increased size of mucocytes along the calicoblastic epithelium in DSS-affected tissues of *S. siderea* suggests the presence of an inflammation response, possibly due to the presence of fungal endoliths. The absence of this response in healthy tissues on affected colonies suggests that inflammation may be localized. The presence of these endolithic cells, coupled with the increased concentration of zymogen granules in adjacent tissues generates questions: is the coral using this digestive enzyme as a defensive mechanism, and does increased concentration of these granules inhibit the endolithic cells or just prevent active invasion of the coral tissue? Although it not yet clear whether the endoliths observed are the causal agents of DSS, our observations suggest that *S. siderea* and *A. agaricites* may utilize a digestive enzyme as a defensive mechanism against endolithic cellular invasion.

The unknowns in coral disease identification: An experiment to assess consensus of opinion amongst experts

A.M.M. Lindop[1], E.J. Hind[1], J.C. Bythell[2]

Abstract: As coral diseases have emerged as a leading cause of mass coral mortality, programmes to research and monitor them have increased. The resultant need to rapidly identify diseases has led to many studies relying on visual analysis and identification of disease. Such approaches have been criticised as subjective and lacking consistency. This study aims to test the level of consistency amongst disease experts by assessing their identification of diseases from a series of photographs. A high degree of variability in almost every photograph was found, with level of observer expertise having no apparent bearing on consistency. It is argued that in order for long term prevalence studies to have meaningful conclusions, standardisation is essential, with recently published coral disease identification guides being a vital step.

Keywords: Coral Disease, Identification

Introduction

Alongside climate change and overfishing, coral diseases are one of the most commonly implicated causes of mass coral mortality (Richardson 1998, Hoegh-Guldberg 1999, Harvell et al. 1999). While partial and whole-colony coral mortality from diseases can act as a natural and sustainable disturbance on coral reefs (Bythell et al. 2000), diseases have in some cases led to long-term, ecosystem-scale impacts. For example, White Band Disease has been implicated in the loss of acroporids as the dominant reef builders in the Caribbean, an unprecedented change within the past 3000-7000 years (Aronson and Precht 2001). Large-scale coral mortality has notable economic impacts for communities reliant on reefs for tourism, fishing and physical protection (Cesar 2002), whilst also contributing to potential phase-shifts and the reduction of reef resilience (Bellwood et al. 2004).

With such serious impacts, it is important that diseases are well studied so that effective management can take place. Yet, despite over 20 years of study, the drivers and dynamics of coral diseases are still poorly understood (CDWG 2007). Whilst it is widely agreed that increased temperature and nutrient enrichment may increase disease prevalence, there is debate as to whether pathogens are acting as primary infectious agents, or are opportunistic, taking advantage of reduced defences of stressed corals (Rosenberg et al. 2007; Lesser et al. 2007). Although over 35 diseases have been described (Lesser et al 2007), etiologies are only understood for five of them, despite considerable recent advances in microbiological techniques (CDWG 2007).

Compounding this lack of understanding is the confusion generated by a lack of rigorous standardisation in disease description and identification. Most monitoring studies do not have the equipment or expertise available for microbial analysis and therefore rely on visual identification (Ainsworth et al. 2007). However, such approaches can be highly subjective and result in errors, a lack of consistency between studies and misidentification (Work and Aeby 2006). Many disease identification guides only provide images of 'classic' well-defined disease symptoms, which means that field workers may not have the diagnostic tools to identify lesions displaying ambiguous symptoms. In these cases, many programmes will still require disease 'identification', perhaps forcing the observer to

categorise disease cases with insufficient or confusing signs. Ainsworth et al. (2007) discovered that what appeared to be a white disease based upon visual morphological characteristics, actually had the microbial characteristics of Black Band Disease, demonstrating that, even aside from subjective errors, visual identification can be unreliable. Regional differences in nomenclature also contribute to variation. For example, swollen pink spots on *Porites* may be called *Porites* trematodiasis in Hawaii, pink spot in Australia, and *Porites* pink blotch disease in Okinawa (Aeby 2006). Highlighting this issue, Richardson (1998) notes that that several coral disease investigators studying an area of reef at the same time named a number of different diseases whilst diagnosing lesions on the same coral colonies.

Recognising the critical nature of accurate field identification, calls have been made to standardise the descriptors of coral syndromes and develop systematic approaches to lesion classification. To this end, Work and Aeby (2006) developed a set of criteria based on the morphological characteristics of a lesion that can be used to describe a syndrome. The most recent system is a handbook and sets of disease identification cards produced by the Coral Disease Working Group (CDWG) that utilise a systematic 'decision tree' approach. This guide is intended to form a standardised guide to identifying, assessing and managing coral reef disease, by providing managers and field surveyors with procedures for describing signs and assessing impacts and giving a standardised approach for recording coral health.

In light of the current debates regarding the best way to monitor coral diseases and the accuracy of visual identification, there is a need to assess the degree of consistency between observers. Therefore, this study aimed to investigate the usefulness of, and provide quantified data on, the level of consistency there is amongst coral disease experts. Using a number of photographs showing a range of coral lesions from different regions, the variation in disease names attributed to each lesion was tested, as well as the extent to which level of expertise affected agreement.

Methodology

The study was conducted through a poster presentation at the 11th International Coral Reef Symposium, Fort Lauderdale, from July 7th to 11th, 2008, as this was where the highest number of disease experts would be present at one time. The poster displayed 23 photographs (Appendix I) showing a variety of coral lesions from the Caribbean and Indo-Pacific regions, but the photograph location was not revealed. One colony photograph of each lesion was displayed and where necessary, an additional close-up showing the polyps was provided. Although it was impossible to select photographs randomly, bias towards 'classic' symptoms, or especially ambiguous samples was avoided and the lesions were chosen for the quality and clarity of the photographs alone. None of the lesions selected had been diagnosed, so there was no 'right' answer to aim for. The images were sourced from the archives of individuals at Newcastle University, UK.

Delegates visiting the poster who had experience of studying diseases were invited to study the photographs and name the disease as best they could. If they were unable to identify the disease, they were advised to leave it blank. The only variable was the level of expertise and respondents were asked to mark one of the five options shown in Table 1. In total, 94 surveys were conducted.

The results were collated according to three different protocols. Firstly, respondent answers were recorded word for word, giving a total of 83 unique descriptions. Secondly, unusual descriptions which had not been heard of were entered into the internet search engine Google Scholar. All descriptions that were not found in publications or monitoring studies were regarded as guesswork and thus re-categorised as 'guess'. Finally, the descriptions that were not a published name, but could reasonably be assumed that the respondent meant a specific disease were grouped into the recognised category. This final data set was analysed in the results.

Table 1: Options for level of coral disease expertise.

1. You have encountered the subject during a short period of academic study or through a brief encounter whilst in the field.
2. You have a couple of weeks experience working on projects in the laboratory or field that have involved disease identification.
3. You have worked on a longer term project(s), encountering a variety of diseases and may have contributed to reports on the topic.
4. Your focus is not coral disease, however, you have spent sustained periods studying coral disease and have produced reports/published on the topic.
5. You have focussed your research in the field of coral disease for a number of years and have published extensively on the topic.

Results

Overall, there was a high variability amongst the respondents when assigning disease descriptions to each photograph, with no photograph receiving less than three descriptions and most receiving over eight (Fig. 1).

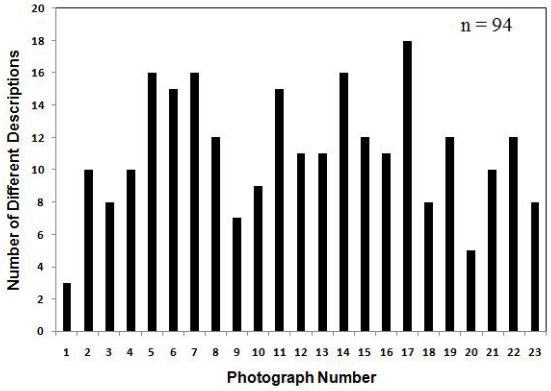

Figure 1: The number of different descriptions assigned to each photograph by whole sample.

This high variability in assigning descriptions to each photograph was also evident within the group of least experienced coral disease experts, with no photograph receiving less than three descriptions and most receiving more than five (Fig. 2). Photograph 17 was assigned eleven different descriptions by respondents, which represents more than one response for every four respondents.

Few signs are shown that consistency of response increases with level of coral disease research experience (Figs. 3 and 4). Despite the sample sizes being lower for the two groupings of respondents with higher levels of coral disease experience there is rarely an increase in response consistency. For instance, the group with most expertise had the highest variance of response for Photograph 5, whilst the group with the least expertise had the lowest variance (Fig. 2). For this photograph those with least expertise (levels 1 and 2) provided approximately one different response for every five respondents, whereas the most experienced (levels 4 and 5) provided a different response for almost every other respondent (Fig. 4). The most experienced respondents also returned a greater number of descriptions than the least experienced group for Photographs 2, 5 and 12, but were most consistent for Photographs 1, 3 and 20.

The spread of disease descriptions for each photograph is shown in Appendix II (Tables 2 and 3).

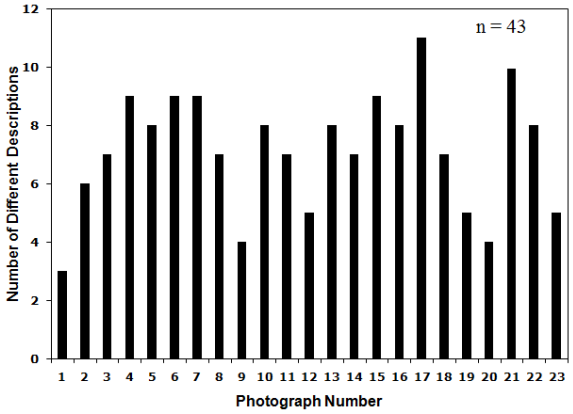

Figure 2: The number of different descriptions assigned to each photograph by respondents - expertise levels 1 and 2.

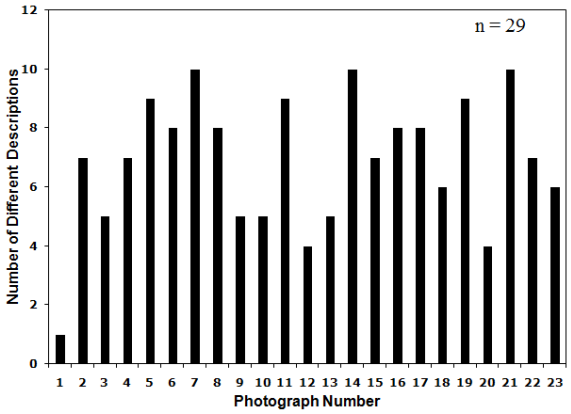

Figure 3: The number of different descriptions assigned to each photograph by respondents - expertise level 3.

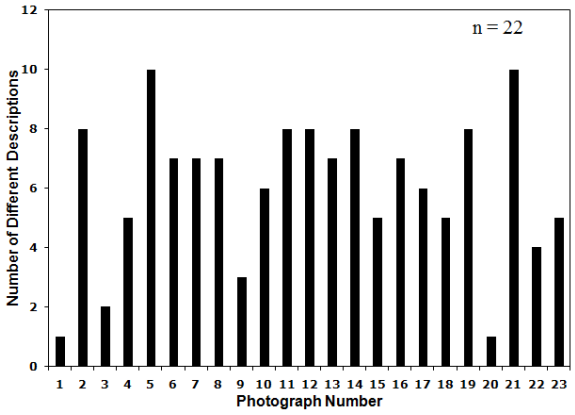

Figure 4: The number of different descriptions assigned to each photograph by respondents - expertise levels 4 and 5.

Some photographs received more consistent overall responses, such as Photograph 1 where 82 of the 94

respondents identified BBD, others identifying brown band and red band (Table 2). Confusion here would appear to be narrowly defined between a range of band diseases, but looking at Photograph 10, it can be seen that confusion can be wider ranging. For this photograph, the most popular responses were bleaching, fish predation and white plague, three syndromes with very different causation (Table 2). Photograph 13 shows that this was also present for the most experienced respondents. In this photograph, experienced respondents were heavily split between a number of white diseases and the very different causation of various predations (Table 3).

Discussion

This study demonstrates that there was a considerable lack of consistency amongst observers when identifying lesions visually. The reason behind such differences is unclear. This could be explained by regional differences in terminology, which are acknowledged to be common (Aeby 2006), and were evident in the initial high number of descriptions. However, this is unlikely to have influenced the final results, as the methods used grouped the similar descriptions in specific categories, which were designed to eliminate such effects as far as possible. The presence of such regional variation raises the question of whether individuals recognise that they are using different names, or whether they regard the different names as different syndromes entirely.

The level of observer expertise did not have a consistent effect on the outcome, so misidentification due to inexperience does not fully explain the results. Although in some cases the more experienced respondents agreed entirely on a specific case description, in others they produced a higher number of descriptions than the least experienced observers. A high degree of variation between observers was therefore likely to be a result of subjective misinterpretation of the information in the photograph, whereby individuals weight syndrome characteristics differently and thus interpret photographs differently.

It is possible that results could have been influenced by how recently an individual was monitoring disease, or by their geographic location. Researchers are more likely to be able to identify diseases in taxa they are familiar with and respondents attempting to identify lesions from unfamiliar regions may explain some of the variability. It is also possible that respondents misrepresented their level of experience, but further study would be required to give clearer answers.

It should be noted that in the field, observers are often looking for a specific set of diseases predefined using histological and microbial tools and will also have more information available than in a two-dimensional photograph, which would probably give *in-situ* observations higher consistency than our results. Also, if using photographs, observers would often have more than one colony photograph providing information, which may improve consistency.

However, it is clear that although the variance of descriptions increases with experience in a few cases, the results strongly suggest that increased training is not the best solution to improve consistency. This highlights the need for standardisation globally, as argued by Work and Aeby (2006). A global standard would go some way to eliminating this variation and reducing the number of descriptions for the same disease.

The results also suggest sizeable problems with attempting to measure disease prevalence changes over time or in larger scale meta-analysis studies. However, progress is being made towards improving this situation and the publication of disease ID guides by the CDWG (2007) offers the beginnings of a solution. If there is widespread adoption of the identification protocols, the likelihood of the misinterpretation and subjective weighting of the importance of lesion characteristics will be reduced and conclusions drawn from monitoring data much more useful for regional and global comparisons. Although such guides will be useful for standardising terminology and field identification, there now need to be studies assessing consistency of identification by observers in the field (i.e. of randomly-selected and representative cases, rather than 'type' cases).

Abstract. Surveys for lesions in corals were conducted at seven sites around Tutuila in June 2004 and January 2005. The objectives of the study were to document the distribution and prevalence of disease in the major genera of corals and crustose coralline algae, systematically describe gross and microscopic morphology of lesions in reef corals and determine whether there are seasonal differences in prevalence of disease. We documented 12 different coral disease states from the reefs of Tutuila and two diseases of crustose coralline algae (CCA). *Acropora* white syndrome, *Acropora* growth anomalies and coralline lethal orange disease were the most common diseases on the reefs of Tutuila. No seasonal differences were found in overall prevalence of coral or abundance of CCA disease. Histological analyses of coral lesions revealed that microscopic changes in tissues can be used to distinguish tissue loss due to trauma from changes due to disease, detect micro-organisms associated with certain types of discolorations and found that hyperplasia of the basal body wall was the hallmark microscopic appearance of *Acropora* growth anomalies regardless of gross morphology of tumors.

Key words: American Samoa, baseline disease surveys, coral disease, crustose coralline algae disease

Introduction

Global climate change and human activities are placing coral reef ecosystems at risk. The effects of over fishing and pollution from agriculture and land development have been a major force accelerating decreases in abundance of coral reef species (Pandolfi et al. 2003). Global climate change is compounding these anthropogenic stressors with increased frequency of bleaching episodes and increases in incidence of coral disease predicted (Hoegh-Guldberg 1999, Hoegh-Gulberg et al. 2007). The reefs of American Samoa have been affected by both natural disturbances (crown-of-thorns starfish invasion, hurricanes and mass bleaching events) and human-induced impacts (pollution and over fishing) (Craig et al 2005). The reefs suffered mass bleaching in 1994 (Goreau and Hayes 1994, Birkeland et al. 2000) with reports of bleaching also occurring in both 2002 and 2003 followed by outbreaks of coral disease (Peter Craig, pers. comm.). Earlier qualitative surveys revealed that diseases are present on coral reefs in American Samoa (Work and Rameyer 2005) but no quantitative baseline coral disease surveys had been conducted. A critical component of monitoring the health of reefs is to have baseline 'before' data with which to compare 'after' conditions (Porter et al. 2001, Santavy et al. 2001). We did baseline disease surveys at seven sites around Tutuila in June 2004 and January 2005. These were prompted by anectodal reports of coral disease outbreaks by local conservation agencies in American Samoa. The objectives of the study were to: 1) document the distribution and prevalence of disease in the major genera of corals and distribution and abundance of disease in crustose coralline algae; 2) systematically describe gross and microscopic morphology of lesions in corals 3) determine whether there are seasonal differences in prevalence of disease.

Methods

The distribution and prevalence of diseased corals and crustose coralline algae were documented at seven sites in American Samoa: Vatia, Tafeu, Fagaitua, Faga'alu, Fagatele Bay, Leone and Maloata. To examine potential seasonal differences in disease levels these sites were surveyed in June 2004 and re-surveyed in January 2005. We documented levels of coral and coralline algae disease at each of the sites using two 25 m belt transects with visual counts. The two transect lines were laid end to end along depth contours separated by approximately 5 meters. A team of two divers swam along the transect, with one diver identifying corals to genus and enumerating colonies, while the other diver recorded presence of

disease. Width of the transect was 1-2 m for colony counts and 6 m for disease assessment. Diseased corals and coralline algae were photographed and a general description of the condition recorded (Work and Aeby 2006, Work and Rameyer 2005). Samples of diseased coral (and healthy portions for controls) were collected for histopathological analyses.

Enumeration of individual CCA colonies was not possible so CCA cover was determined using the point-intercept method whereby the substratum underlying the tape measure was recorded at set intervals. At each site one to two stations were surveyed depending on time availability.

For histopathology, corals were processed using standard techniques and stained with hematoxylin and eosin. Special stains were used as appropriate to identify fungi, bacteria, algal filaments, or protozoa. On histology, lesions were classified as depletion of zooxanthella, atrophy, uncomplicated necrosis, necrosis associated with fungi, algae, protozoa, or metazoa, and hyperplasia of basal body wall.

For corals, prevalence of lesions was calculated by extrapolating colony counts within the 25 X 1 m transect to the wider 25 X 6 m disease survey area and using this as the denominator of prevalence calculations, e.g. (number of colonies with lesions/total number of estimated colonies)* 100. Abundance of CCA disease was determined by calculating the number of CCA lesions per square meter of CCA surveyed. Frequency of disease occurrence (FOC) was defined as the number of sites having corals or CCA with disease (within or outside of transects)/ total number of sites surveyed. FOC reflects the spatial distribution of diseases on reefs. Data were not normally distributed even with transformation so a Wilcoxon signed rank test was used to test for seasonal differences in coral disease prevalence and CCA disease abundance. For each survey period (2004 and 2005), a chi square homogeneity test was used to look for differences in the distribution of the number of diseased vs. healthy colonies among the six most common scleractinian genera (*Acropora, Pavona, Porites, Pocillopora, Montipora, Leptastrea*)

Results

Overall occurrence of disease

During surveys in 2004 and 2005, twelve different coral disease states (or lesion types) were documented from eight coral genera on the reefs of Tutuila (Table 1). Coral disease was found at all seven sites each year but the overall proportion of colonies examined that had lesions (prevalence) was low (avg.=0.18%) (range=0.04-0.36%) (Table 1). There were two diseases of crustose coralline algae (CCA) found: coralline lethal orange disease (CLOD) (Littler and Littler 1995) and CCA black fungal disease (Littler and Littler 1998).

Distribution, frequency of occurrence and prevalence of each disease state

Distribution and prevalence of diseases in corals and CCA varied among sites (Table 1). *Acropora* white syndrome (AWS) and *Acropora* growth anomalies (AGA) were the most widespread diseases. AWS was found at 5 of 7 sites (FOC=71.4%) and AGA was found at 4 of 7 sites (FOC=57.1%). The overall prevalence (all sites combined) of each disease was averaged between years and revealed that *Porites diffuse* tissue loss, *Acropora* growth anomalies and *Acropora* tissue loss to be the most commonly encountered lesions (Table 1). Prevalence of *Lobophyllia* diffuse tissue loss, *Pavona* growth anomalies and *Goniastrea* growth anomalies were not calculated as the diseases were present at the study site but not within the belt transects.

CLOD was a common CCA disease found at 4 of the 7 sites (57%) in 2004 and 43% of the sites in 2005 whereas CCA black fungal disease was only found within Fagatele Bay. The number of CLOD infections per m^2 of CCA ranged from 0 to 0.37 and the number of CCA black fungal disease within Fagatele Bay was 0.003 infections per m^2 of CCA.

Difference in disease levels among coral genera

Prevalence of disease differed among the coral genera within each year surveyed (2004: X^2=113.0 df=5, p=0.00; 2005: X^2=29.06, df=5, p=0.00). Of the six most abundant scleractinian coral genera found within our transects, *Acropora* had the highest average prevalence (0.85%) followed by *Pavona* (0.14%), *Porites* (0.11%), *Montipora* (0.06%), *Leptastrea* (0.06%) and *Pocillopora* (0%). One colony with growth anomalies was found in *Goniastrea* and a single colony with diffuse tissue loss in *Lobophyllia* but no signs of coral disease were found in any of the other coral genera that were surveyed.

Seasonal differences in coral and CCA disease on Tutuila

There were no seasonal differences found in coral disease prevalence or CLOD abundance. Average coral disease prevalence was 0.21% (SE$\pm$0.08) in Winter 2004 as compared to 0.15% (SE$\pm$0.05) in Summer 2005 (Wilcoxon signed rank, n=14, p=0.29). CLOD levels were 0.039 (SE$\pm$0.03) CLOD/m^2 CCA in winter as compared to 0.049 (SE$\pm$0.03) in summer (Wilcoxon signed rank, n=14, p=0.88).

Table 1. Prevalence and distribution of lesions in corals and distribution and abundance of lesions in crustose coralline algae. 'X' indicates presence of a lesion at a site outside of the survey area. Data show average prevalence (%) of coral lesions or abundance of lesions for CCA (# lesions/m^2) from surveys in 2004 & 2005 in Tutuila, American Samoa.

	avg. overall prevalence (±SE)	SITES

CCA black fungus (# lesions/m^2 CCA)						0.003		

Histology

We examined tissue specimens from 100 colonies comprising at least 30 species of corals. In some instances, tissue loss in corals was explained by presence of feeding fish (fish bites) or encrusting organisms (barnacles or sponges). Histology in such cases, usually showed abrupt cessation of tissue. In contrast, tissue loss of unexplained etiology (potential disease lesions) usually showed necrosis sometimes associated with algae or sponges. A single plating *Acropora* with a distinct circular pattern of tissue loss revealed microscopic evidence of ciliate invasion into tissues. The gross lesion, as well as the microscopic evidence (ciliates), were both distinct from AWS. Discoloration in corals took two forms (pale and dark purple). The pale discoloration found in *Favia/Favites* was, on microscopy, attributed to mucus sheathing and not considered abnormal. Presence of diffuse, irregular dark purple discoloration in *Pavona* and *Pssamocora* were attributed to overgrowth of skeleton by endolithic fungi leading to necrosis of overlying tissues a disease we term endolithic hypermycosis (Work et al. 2008b). Growth anomalies in both acroporids and montiporids showed proliferation (overgrowth) of the basal body wall. .

Discussion

From surveys in June 2004 and January 2005 we documented 12 different coral disease states from the reefs of Tutuila and two diseases of crustose coralline algae (CCA). *Acropora* white syndrome (AWS), *Acropora* growth anomalies (AGA) and CLOD were the most common diseases on the reefs of Tutuila. White syndrome (defined as focal to multifocal to diffuse, acute to subacute, tissue loss) in *Acropora* is widespread across the reefs of the Indo-Pacific, and has been found from Australia (Willis et al. 2004) out to the remote reefs of the Northwestern Hawaiian Islands (Aeby 2006a, Aeby 2006b). In some regions, white syndrome in acroporids and other coral genera is presumably caused by bacteria within the family Vibrionacae (Sussman et al. 2008). Whether this is the case in other regions remains to be confirmed and further studies are currently underway to examine potential causes of AWS within American Samoa which should shed light on whether the underlying etiology of AWS is similar across regions within the Indo-Pacific.

Acropora growth anomalies (AGA) were common in Tutuila, which is in contrast to the GBR where they are seldom found even though acroporids are the dominant coral (Willis et al. 2004). Work et al. (2008a) compared AGA levels in American Samoa, Johnston Atoll and the northwestern Hawaiian Islands and suggested that occurrence of AGAs may be influenced by environmental factors. Similarly, the occurrence and rate of progression of black band disease are influenced by reduced water quality (Kaczmarsky et al. 2005, Voss et al. 2006).

CLOD, a bacterial disease that kills coralline algae, was originally reported from the Cook Islands in 1993 and subsequently spread throughout the South Pacific including American Samoa where it was first observed in 1995 (Littler and Littler 1995). We found that it is still common on the reefs off Tutuila suggesting it is a chronic disease on these reefs. The black fungal disease found on CCA has a limited distribution in the Indo-Pacific and has only been reported from Tutuila, American Samoa (Littler and Littler 1998).

Prevalence of coral disease was found to be low (avg. <1%) on the reefs of Tutuila, which contrasts with other studies. Dalton et al. (2006)

found disease prevalence ranging from 6.21% to 13.6% on reefs in the Solitary Islands, Australia. Raymundo et al. (2005) surveyed two regions in the Philippines and found the mean disease prevalence to be 8.3%. However, Haapkyla et al. (2007) surveyed reefs in southeast Sulawesi, Indonesia and reported overall prevalence to be 0.57%. Why some regions within the Indo-Pacific seem to be more affected by coral disease than others is still unknown. Coral disease research is in its infancy in the Indo-Pacific and more information is needed on the ecology and causes of coral diseases in order to properly interpret the patterns encountered in the field.

We found *Acropora* to be disproportionately affected by disease in Tutuila. *Acropora* appear to be particularly susceptible to disease and this same pattern is emerging Indo-Pacific wide being found on the GBR (Willis et al. 2004), Sulawesi, Indonesia (Haapkyla et al. 2007) and the northwestern Hawaiian Islands (Aeby 2007). *Acropora* are also highly susceptible to bleaching (Marshall and Baird 2000) and so should be monitored closely in the Indo-Pacific as we face future problems associated with global climate change. Increased sea surface temperatures as well as ocean acidification are predicted with global climate change as well as the resultant increases in coral bleaching and disease (Hoegh-Guldberg 1999, Hoegh-Gulberg et al. 2007).

Seawater temperature can influence disease occurrence. For example, black band disease in the Florida Keys is much more common in the warm summer months and virtually disappears from the reefs during the colder winter months (Kuta and Richardson 1996). In contrast, we found no seasonal differences in overall level of coral or CCA disease for any of the diseases in American Samoa. In Hawaii, the coral disease *Porites* trematodiasis also showed no seasonal variation (Aeby 2007). Differences in seasonal variation among coral diseases may be partially explained by degree of temperature fluxuation within the different regions. For example, the sea surface temperature (SST) in America Samoa only varies between seasons by approximately 2 degrees Celsius whereas in the Florida Keys, SST can vary up to 10 degrees Celsius. Perhaps the small seasonal differences in SST in American Samoa do not affect disease levels as strongly as found in other regions. During the two time periods that we conducted our surveys, the average SST varied by less that one degree Celsius. However, the manner in which a disease responds to a specific environmental stressor will also depend on what is causing the disease (etiology) and the host affected by the disease.

Histology proved to be a critical tool in understanding disease processes and allowed for the the detection of potential causative agents of lesions, particularly in cases where gross lesions had no obvious explanation in the field. For example, tissue loss due to trauma (either through predation or other insult) could be differentiated from tissue loss due to disease based on microscopic changes in tissues such as necrosis and presence or absence of associated factors such as algae, sponges, fungi, or protozoa. We also found that the mottled discoloration observed in faviids was associated with normal mucus sheathing. In some cases, histology also proved useful in understanding the potential etiology of a gross lesion. Dark purple discoloration observed in *Montipora* and *Pavona* was found to be associated with overgrowth of endolithic fungi (Work et al. 2008b). On the other hand, some corals manifesting different types of lesions grossly, had similar microscopic manifestations. For example, six distinct morphological types of growth anomalies were found in *Acropora*, yet on histology, hyperplasia of the basal body wall with absence of or reduced polyp formation was found to be the consistent microscopic change for all types of GA types suggesting perhaps a similar underlying etiology (Work et al. 2008a). In contrast, Domart-Coulon et al. (2006) found normal polyp development in *Porites* growth anomalies emphasizing the utility of histopathological analyses in understanding coral lesions. Comparing in situ photographs with follow-up histological analyses on lesions also provides the opportunity for a more accurate interpretation of lesions in corals in the field.

Future efforts should concentrate on elucidating the mechanisms and potential causes of major diseases on reefs from American Samoa. Given their frequency of occurrence, two candidate diseases for such studies would include growth anomalies and white syndrome in *Acropora* sp.

Acknowledgements The American Samoa coral reef advisory group funded this work. The National Park Service of American Samoa and the American Samoa Department of Marine and Wildlife Resources provided critical logistical support.

Abstract. *Vibrio* strains previously isolated from Caribbean yellow band (CYBD) diseased *Montastraea faveolata* from Puerto Rico were combined into metabolically similar groups based on biolog data (P1, similar to *Vibrio campbellii*; P2, similar to *V. splendidus* and P3, similar to *Aeromonas trota*). Bacterial groups were inoculated onto healthy *M. faveolata* colony fragments that were aerated in individual plastic containers exposed to two temperature regimes (28ºC and 31ºC). Coral genets were divided into two groups of five and maintained at either 28ºC or 31ºC. Three fragments were inoculated with bacterial groups P1, P2, or P3, and two were used as delivery medium or water/container controls at each temperature. Corals were monitored for ten days. After Day 1, two fragments inoculated with P1 and maintained at 31ºC showed signs of yellowing tissue similar to initial stages of CYBD. Three fragments inoculated with P2 and held at 28ºC showed similar signs of paling to yellowing tissue. Two additional fragments showed signs at Day 2 (P1 and P2 at 28ºC). At Day 5, two more P1 inoculated fragments showed disease signs (one at 31ºC and one at 28ºC). Genetic identification of isolates from each group show that members of group P1 are most similar to *V. cambellii* and members of group P2 are most similar to *Photobacterium eurosenbergii*. These preliminary results indicate that more than one type of *Vibrio* sp. may be able to initiate signs of disease and/or bleaching and no clear patterns in response were associated with temperature under the experimental conditions.

Key Words: Yellow band, *Vibrio*, *Montastraea faveolata*, coral disease

Introduction

Among the deleterious effects of climate change on coral reefs has been the increase of coral diseases (Harvell et al. 2004, 2007). Caribbean yellow band disease (CYBD) is particularly prevalent in the Caribbean (Ward et al. 2006; Weil et al. 2006; Weil and Croquer unpub. data), and a similar syndrome occurs in the Indo-Pacific. This disease is temperature influenced (Cervino et al. 2004a), appears to affect zooxanthellae (Cervino et al. 2004b), and is closely associated with species in the genus *Vibrio*. This study tested the pathogenic potential of *Vibrio* isolates obtained from CYBD-infected *Montastraea faveolata* colonies from the south coast of Puerto Rico.

Material and Methods

Bacterial isolates were obtained by SCUBA from CYBD affected *Montastraea faveolata* near La Paguera, Puerto Rico. Samples of the surface mucus and associated coral tissue were collected and *Vibrios* isolated as described in Cunning et al. (this issue). Each isolate was characterized using Biolog™ (Heyward, CA) and identified by sequencing the small subunit 16S rRNA gene as described in Cunning et al (this issue). Isolates were chosen for inoculation based on similarities to isolates previously described (Cervino et al. 2004a) and isolates that were unique to diseased colonies. Isolates fell into one of three groups, corresponding to *Vibrio harveyi/V. campbellii* (P1), *V. splendidus/Photobacterium eurosenbergii* (P2), or *Aeromonas trota/P. eurosenbergiii* (P3) based on carbon source utilization patterns obtained from Biolog™ plates or 16S rDNA sequencing BLAST results, respectively.

Two isolates were used in the P1 group inoculations (3A8 and 1B4), three in P2 (3B7, 1H5 and 3F8) and two in P3 (1A9 and 2H12). Biolog profiles, genetic identities, and GenBank Accession numbers are shown in Table 1. The inocula were made by growing each isolate overnight in GASW broth at 32°C, then combining (1.5ml of each isolate for P1 and P3 and 1.0ml of each isolate for P2) in a test tube with 1g of sterile sieved calcium carbonate sand, shaken, and allowed to absorb on the sand particles overnight (described in Patterson et al. 2002). Ten replicates were made for each inoculum (P1, P2, P3, and controls). Before inoculation, excess medium was decanted and

replaced with sterile seawater. Controls were treated similarly except sterile sand with uninoculated sterile media was used.

Coral fragments were obtained from healthy *M. faveolata* colonies using a hammer and chisel. Fragments were left to acclimate in the field for three days after which each of the 40 fragments were retrieved, tagged, placed in individual aerated containers in a heated water bath either at 28ºC or at 31ºC (Fig.1). Fragments were acclimated in tanks for 24 hours prior to experimental onset. Salinity was checked twice a day and sterile seawater added as needed. Temperature was monitored at least three times a day. An extra five fragments were placed in each temperature, but left untreated. Treatments for each of the coral fragments used in this experiment were randomly assigned. The treated sand grains were poured directly onto the coral fragments. As sand grains were removed from the surface by the corals, inoculate was replaced twice a day using labeled droppers for two days (Fig.2). Observations on yellowing (paling) were made daily (Fig. 3) and the experiment was run for 12 days.

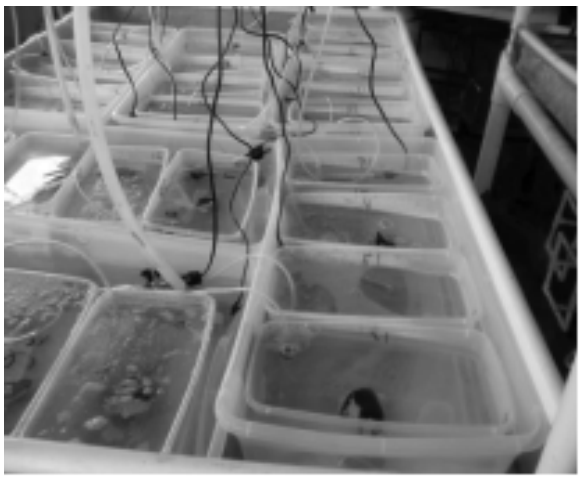

Figure 1: Experimental set up.

Results

Bacteria phylogenetically identical to *Vibrio* spp. previously implicated in YBD (Cervino et al. 2004a) were not identified in the accompyaning study (Cunning et al. this issue). Therefore, *Vibrios* unique to diseased coral that also showed similar carbon source utilization profiles to *Vibrio* species in the Cervino et al. study were subdivided into groups P1-P3 and used in inoculation experiments in this study (Table 1). P1 isolates had slightly different metabolic profiles but were identical to *V. harveyi and V. campbellii*, based on 16S rDNA sequencing results. P2 and P3 isolates were phylogenetically most similar to *Photobacterium eurosenbergii* (Table 1).

Figure 2: Replacement of carbonate inoculate.

After the first day of incubation, two fragments inoculated with group P1 showed yellowing (Fig.3) but only in those fragments incubated at 31ºC.

Conversely, three of the five replicates inoculated with P2 showed yellowing, but only with fragments incubated at 28ºC. This increased to four of the five for P2 (28ºC) on day two and one fragment from P1 (28ºC). On day three, one fragment from the P2 (31ºC) and one from P3 (31ºC) showed yellowing signs. This increased to three of the five for P3 (31ºC) and one for the control (31ºC) on day four. By day 5, all of the P2 (28C) fragments showed signs of yellowing, as well as an additional fragment from P1 (28ºC), P1 (31ºC), P3 (28ºC) and P3 (31ºC). Two additional fragments from the control (31ºC) also showed yellowing by day 5. Throughout the five day period, all fragments from the control (28ºC) remained healthy as did the untreated fragments.

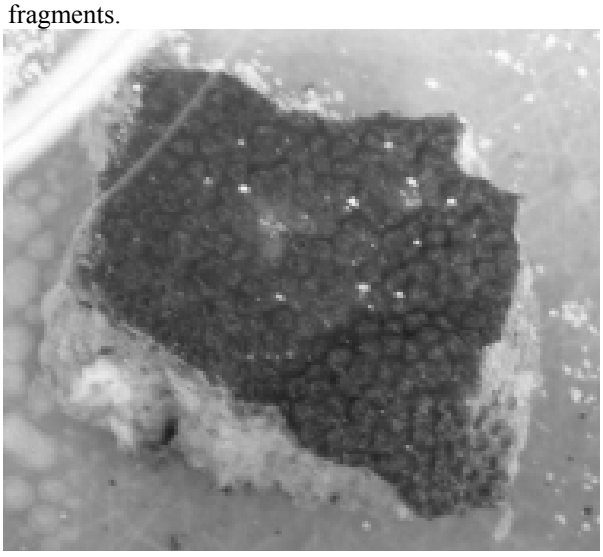

Figure 3: Potential CYBD signs three days after inoculation.

Table 1: Isolates used in Inoculations

Group	Isolate	Biolog™ (Similarity)	% ID based on Genetic Analysis	GenBank Acc#
P1	3A8	*Aeromonas enteropelogens* (0.300) *Vibrio campbellii* (0.130)	100% *Vibrio harveyi/V. campbellii*	FJ356774
P1	1B4	*V. campbellii* (0.230) *Vibrio proteolyticus* (0.280)	100% *Vibrio harveyi/V. campbellii*	EU854881
P2	3B7	*Vibrio splendidus* (0.580) *V. splendidus* (0.770)	100% *Photobacterium eurosenbergii*	FJ356775
P2	1H5	*V. splendidus* (0.500) *V. splendidus* (0.680)	100% *P. eurosenbergii*	EU854888
P2	3F8	*V. splendidus* (0.780) *V. splendidus* (0.410)	100% *P. eurosenbergii*	EU854889
P3	2H12	*Aeromonas trota* DNA group 13 (0.200) *Aeromonas trota* DNA group 13 (0.310)	100% *P. eurosenbergii*	EU854887
P3	1A9	*Aeromonas trota* DNA group 13 (0.250) *Aeromonas trota* DNA group 13 (0.330)	100% *P. eurosenbergii*	EU854886

Although we report here results from the first five days after treatment, the trials were run for twelve days. On day six all fragments in the 31°C table appeared unhealthy (paled) so the heaters were turned off. By day twelve all fragments were unhealthy and the experiment was terminated. Comprehensive results of all inoculations are shown in Figure 4.

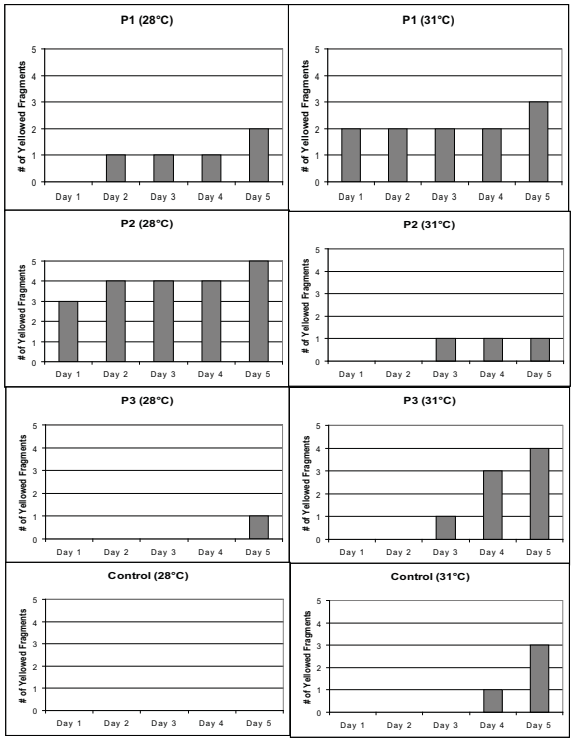

Figure 4: Number of coral fragments showing signs of yellowing over the five day incubation period. Those on the left were kept at 28°C and those on the right at 31°C. P1, P2, and P3 are bacterial inoculants.

Discussion

Of important note is that although isolates chosen for inoculation experiments were identical based on 16S rDNA sequences in the case of Group P1 (*V. harveyi/V. campbellii*) and groups P2 and P3 (*P. eurosenbergii*), however these strains were metabolically different as illustrated by Biolog results (Table 1). This suggests that phylogenetically similar isolates are different strains that could additionally have varying phenotypes with respect to pathogenic mechanisms. Results indicate that, under the experimental conditions, inoculations with one or more of the three bacterial strains in P1 results in yellowing in corals at 31ºC. However some fragments showed yellowing, although to a lesser extent, at 28ºC. A surprising result was that the bacteria in the P2 inoculants greatly hastened yellowing at 28ºC but, conversely, displayed yellowing to a lesser degree at 31ºC. P3 inoculations hastened signs of yellowing by one day at the higher temperature but did not appear significantly different from controls.

Of interest is the potential role of one or more bacteria in the P2 group which hastens yellowing at lower temperatures, but appears to arrest yellowing at higher temperatures. These results suggest that the role of temperature in *Vibrio*-coral interactions may be more complex than previously described.

Abstract. Bacteria of the genus *Vibrio* have been implicated in coral bleaching as well as diseases, including Caribbean Yellow Band Disease (CYBD). Four *Vibrio* species have been previously identified as causative agents of CYBD through a series of infection and re-isolation experiments. The mechanisms of pathogenesis and the dynamics of the *Vibrio* community as a whole during CYBD infection are poorly understood. In order to elucidate the role of *Vibrios* in CYBD, a survey of *Vibrio* species associated with healthy corals and CYBD-infected corals was conducted using a culture-based approach. Fragments were collected from CYBD lesions of five *Montastraea faveolata* colonies, five healthy regions of the same diseased colonies, and five entirely healthy colonies. Samples were serially diluted and plated onto TCBS agar to differentially select for *Vibrio* species. Colonies were subcultured using GASWA media and a total of 391 isolates were identified by 16S rDNA sequence analysis. Phylogenetic analysis of *Vibrio* spp. communities of healthy and diseased corals illustrated a shift from isolates taxonomically affiliated with *V. fortis* dominating in healthy corals to isolates taxonomically affiliated with *V. harveyi,* a known marine pathogen, dominating in diseased corals. There was a similar shift to isolates taxonomically similar to *Photobacterium eurosenbergii* as corals progressed to diseased states. However, our study did not find any *Vibrio* species that are always present in CYBD lesions and absent from healthy samples.

Key Words: Yellow Band Disease, *Vibrio*, *Montastraea faveolata*, coral disease

Introduction

Coral reefs worldwide are declining in response to a number of threats, including bleaching and disease (Harvell et al. 1999, 2007). The susceptibility of corals to these threats involves complex interactions among environmental conditions, the coral animal, and its associated algae and bacteria. Some coral-associated bacteria benefit their hosts by providing energy and nutrients and inhibiting pathogens, while others are implicated in coral bleaching and diseases (Rosenberg et al. 2007).

One of the major types of bacteria associated with corals is *Vibrio*. Members of the genus *Vibrio* are highly abundant in the marine environment, and are found in association with a variety of organisms (Thompson et al. 2004). Several *Vibrios* are pathogenic to marine organisms, including *V. harveyi*, which has been implicated in diseases of fish (Ishimaru and Muroga 1997), shrimp (Alvarez et al. 1998), lobsters (Diggles et al. 2000), seahorses (Alcaide et al. 2001), and echinoderms (Becker et al. 2004). *Vibrios* are consistently found in association with apparently healthy corals (Ritchie and Smith 2004; Bourne and Munn 2005; Ritchie 2006), although some have been implicated in coral bacterial bleaching and disease. Ritchie et al. (1994) demonstrated a shift to *Vibrio* dominance in the bacterial communities of bleached corals (>60% *Vibrio*), followed by a return to initial values (~25% *Vibrio*) upon recovery. Apparently healthy non-bleached coral tissue also becomes dominated by *Vibrios* under conditions of increased temperature, suggesting that a shift to *Vibrio* dominance in response to temperature may precede bleaching (Ritchie 2006). Other studies have demonstrated that *V. shiloii* and *V. coralliilyticus* are causative agents of bacterial bleaching in the corals *Oculina patagonica* and *Pocillopora damicornis*, respectively (Kushmaro et al. 1996; Ben-Haim et al. 2003).

In addition to bacterial bleaching, a number of coral diseases have been associated with *Vibrio* species, including white pox, and white syndrome (Rosenberg et al. 2007), gorgonian disease (Hall-Spencer et al. 2007), skeletal tumors in the coral *Porites compressa* (Breitbart et al. 2005), and Caribbean Yellow Band Disease (CYBD) in *Montastraea* spp. (Cervino et al. 2004b).

CYBD has been documented in *Montastraea* spp. around the Caribbean and manifests as pale yellow blotches or bands that spread over the surface of the

coral (Cervino et al. 2004b). Cervino et al. (2004b) identified four *Vibrio* species as causative agents of CYBD through a series of infection and reisolation experiments. The authors suggest the four *Vibrios* act together with *V. alginolyticus* to affect the corals' symbiotic algae and that degradation of zooxanthellae *in situ* results in the pale yellow bands observed on infected Caribbean and Indo-Pacific corals (Cervino et al. 2008). In this study we characterized differences in culturable *Vibrio* communities of healthy and CYBD affected corals.

Materials and Methods

Montastraea faveolata samples were harvested from five entirely healthy colonies (HEA group; HEA-1 to HEA-5), five colonies with CYBD lesions (DIS group; YBD-1-D to 5-D), and five healthy regions of the same diseased colonies (^{H}DIS group; YBD-6-H to 10-H). In addition, one diseased *M franksii* was included in this analysis (YBD-11-D). Sampling was conducted at 10-12m depth at Turrumote reef (17º56.097'N, 67º01.130'W), off La Parguera Natural Reserve on the southwest coast of Puerto Rico in July 2007. Water temperature at the time of sampling was 29.2°C. Samples were shipped overnight to Mote Marine Laboratory, Sarasota, FL, where mucus samples were removed, serially diluted and plated onto thiosulfate-citrate-bile salt (TCBS) agar to differentially select *Vibrios*. Vibrio colonies were then subcultured using glycerol artificial seawater agar (GASWA; Smith & Hayasaka 1982) and 391 isolates were selected for genetic analysis. DNA was extracted by boil lysing in 100 µL of sterile water at 95°C for 10 minutes. PCR amplification of the 16S rRNA gene was carried out in 50 µL reactions using 1x PCR buffer (Qiagen), 200 µM of each deoxynucleotide (Qiagen), 2 µM each of 16S rRNA primers U9F (5'-GAGTTTGATYMTGGCTC-3') and U1509R (5'-GYTACCTTGTTACGACTT-3') (Invitrogen), 1U Taq polymerase (Qiagen), and 2 µL DNA template. Thermocycling began with an initial denaturation step at 95°C for 3 min, followed by 30 cycles of denaturation at 95°C for 30s, annealing at 50°C for 30s, and extension at 72°C for 90s, with a final extension step at 72°C for 10 min. Amplification of a ~1500 bp fragment was confirmed by electrophoresis on a 1% agarose gel. PCR products were sequenced by Macrogen, Inc (Korea). Consensus sequences from forward and reverse strands were generated and GenBank BLAST searches were performed to demonstrate percentage identity to known bacteria. Sequences were aligned using CLUSTAL X version 1.83 and the ends were trimmed resulting in ~1325 bp sequences for phylogenetic analysis. A pairwise comparison was used to eliminate duplicate sequences. In accordance with current *Vibrio* taxonomical standards (Kita-Tsukamoto et al. 1993, Thompson et al. 2005) sequences with >99.3% similarity were considered representatives of the same taxon and sequences were grouped by this criterion for phylogenetic analysis. Neighbor-joining dendrograms were constructed using MEGA software (v.4) with bootstrap values based on 1000 replicates. GenBank Accession numbers are as follows: DIS (EU854819-EU854889, and FJ356774-5), ^{H}DIS (EU517610-EU517657) and HEA (EU854890-EU854953).

Results

A total of 391 16S rRNA gene sequences were obtained from bacterial isolates, 215 from DIS samples, 108 from ^{H}DIS samples, and 68 from HEA samples. Successful sequences were derived from a very small proportion of 2 of the 5 HEA samples (Fig. 2). For this reason, these data were omitted to avoid statistical error.All sequences were taxonomically similar to five *Vibrio* taxa: *V. harveyi*, *V. fortis*, *V. brasiliensis*, *V. chagasii*, and *Photobacterium eurosenbergii* (Fig. 1). Isolates similar to *V. brasiliensis* and *V. chagasii* constituted 0.47% and 3.74% of DIS isolates, respectively, but were not present in ^{H}DIS or HEA samples. Isolates taxonomically similar to *P. eurosenbergii* made up 3% and 4% of DIS and ^{H}DIS samples, respectively, but were not present in HEA samples. *V. fortis*- and *V. harveyi*-like isolates were present in all three groups, with those similar to *V. fortis* constituting 69% of HEA isolates, 58% of ^{H}DIS isolates, and 47% of DIS isolates, and those taxonomically similar to *V. harveyi* constituting 31% of HEA isolates, 38% of ^{H}DIS isolates, and 45% of DIS isolates (Fig.1).

Due to considerable variation in the relative proportions of *Vibrio* taxa among individual samples within each group (Fig. 2) there were no significant differences in mean proportions of taxa among groups. Among DIS samples, the proportion of *V. harveyi*-like isolates ranged from 0.161 to 0.788 (mean=0.447±0.096), and that of *V. fortis*-like isolates ranged from 0.212 to 0.742 (mean=0.491±0.095). *V. chagasii*-like isolates were present only in sample YBD-1-D, and *V. brasiliensis*-like isolates were only present in sample YBD-3-D. *P. eurosenbergii*-like isolates were present in every DIS sample except YBD-3-D and YBD-11-D. Among ^{H}DIS samples, the proportion of *V. harveyi*-like isolates ranged from 0.154 to 0.522 (mean=0.330±0.071), and that of *V. fortis*-like isolates ranged from 0.435 to 0.818 (mean=0.632±0.071). *P. eurosenbergii*-like isolates were present in all ^{H}DIS samples except YBD-7-H. Only the HEA samples showed any consistency, with *V. fortis* dominating and *V. harveyi* being the only other isolate present in all three samples. A fourth healthy colony was sampled but not included in analysis because from it only five sequences were ob-

tained. However, it is worth noting that a sequence similar to *Vibrio coralliilyticus*, a known coral pathogen, was found in this sample.

Discussion

In this study we have addressed culturable members of the genus *Vibrio* for analysis. Although it is estimated that less than 1% of bacteria can be cultured in the laboratory, culture based work is the only way to address pathogenesis in coral diseases. Drawbacks to this work include an inability to culture various *Vibrios*, which could enter a viable but non-culturable state during infections rendering them non-detectable using these methods. We would stress that this study does not provide quantitative data of *Vibrios* present, but only an estimate of proportional abundance. When sequences are pooled into DIS, ^{H}DIS and HEA groups (Fig. 1), several differences are apparent. First, the proportion of *V. harveyi*-like sequences is lowest in the HEA group, higher in ^{H}DIS, and highest in DIS, indicating that *V. harveyi*-like isolates become more abundant as the disease progresses. *V. harveyi* has been shown to be a pathogen to many marine organisms (Austin and Zhang 2006) and produces a variety of toxins including haemolysins (Zhang et al. 2001), which can lyse cells and cause tissue damage (Zhang and Austin 2005). Involvement of these haemolysins in CYBD etiology would account for tissue lesions observed on infected corals and would support indications that lysis of zooxanthellae may be a potential disease mechanism (Cervino et al. 2004a, b). However, *V. harveyi* is also found in healthy corals (present study and Ritchie 2006), thus any involvement in CYBD must be opportunistic or mediated by a mechanism such as quorum sensing (Thompson et al. 2004).

In addition to an increase in *V. harveyi*-like isolates as corals progress to diseased states, there is a concurrent decrease in *V. fortis*-like isolates, suggesting *V. fortis* may be a dominant and innocuous member of the healthy *Vibrio* community that is outcompeted as the disease progresses. However, *V. fortis* has also been shown to be a pathogen to both fish and crustaceans (Austin et al. 2005). Additionally, an isolate with >99.5% 16S sequence similarity to *V. fortis* has exhibited algicidal activity (Imai et al. 2006), which is

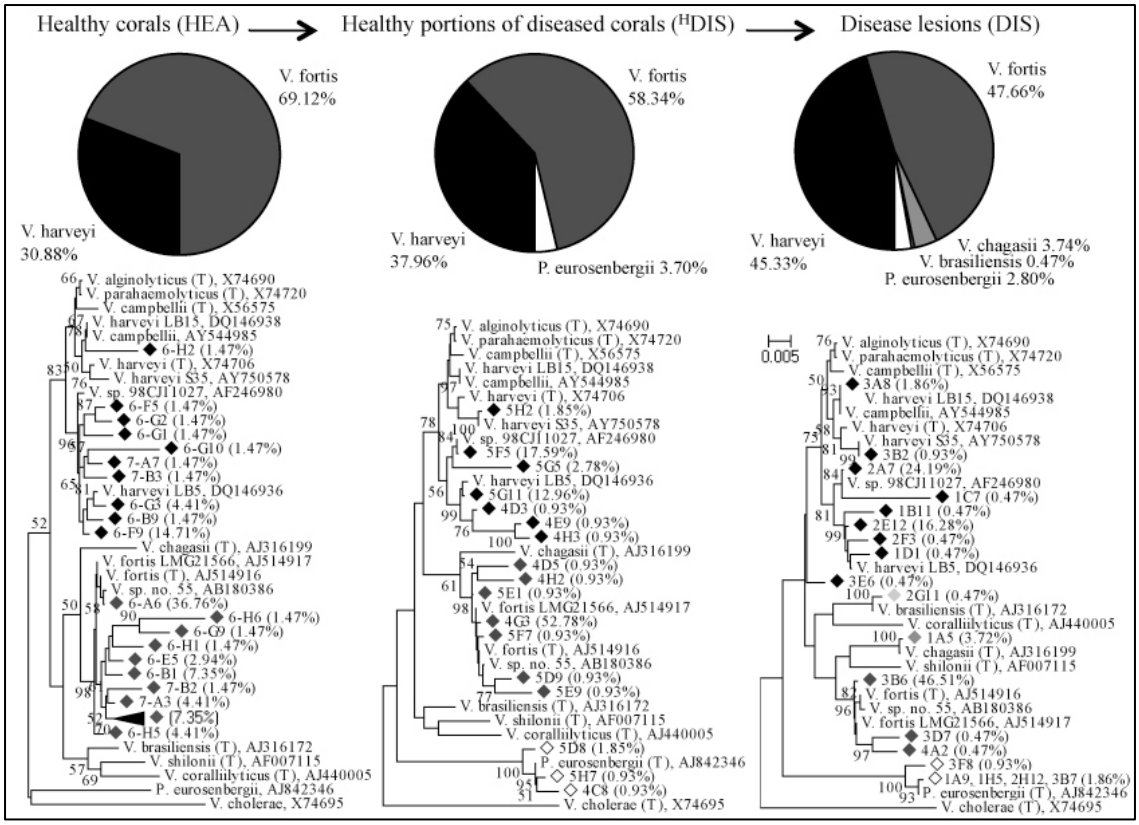

Figure 1. Phylogenetic trees and pie charts representing phylogenetic positions and relative abundances of major groups of *Vibrio* isolates identified from HEA, ^{H}DIS, and DIS groups by 16S rDNA sequence analysis of cultured isolates. Branches marked by diamonds represent sequences from the present study (Genbank accession numbers EU854819-EU854953). Percentages indicate the proportion of sequences in that group that are >99.3% similar. Other sequences included are the closest matches from GenBank, (T) indicating type strain. Dendrograms were created in MEGA (version 4) using the Neighbor-Joining method. Numbers at the nodes indicate the level of bootstrap support (%) from 1000 replicates. The evolutionary distances were computed using the Maximum Composite Likelihood method and the scale represents 0.005 substitutions per site. All positions containing alignment gaps and missing data were eliminated only in pairwise sequence comparisons (pairwise deletion option). Pie charts represent the proportion of all sequences from HEA, ^{H}DIS, or DIS groups that match most closely to *V. harveyi, V. fortis, V. brasiliensis, V. chagasii,* or *P. eurosenbergii*.

a proposed mechanism of CYBD infection (Cervino et al. 2004a, b). However, as *V. fortis* was dominant in healthy corals in this study, its involvement in CYBD must also be opportunistic.

In addition to having more *V. harveyi*- and less *V. fortis*-like sequences, the DIS group contained sequences similar to *V. brasiliensis* and *V. chagasii* that were not present in ^{H}DIS or HEA samples. *V. brasiliensis,* isolated first from bivalve larvae (Thompson et al. 2003) is closely related to the oyster pathogen *V. tubiashii* and the coral pathogen *V. coralliilyticus* (Thompson et al. 2004) and has been shown to be pathogenic to fish and crustaceans (Austin et al. 2005). *V. chagasii* is a chitonlytic bacterium that has been isolated from the gut of turbot larvae (Thompson et al. 2003) and coastal fishes (Itoi et al. 2006). The presence of these sequences only in DIS samples is consistent with increased bacterial diversity observed in other coral diseases (Pantos et al. 2003).

Another difference among the three groups was the presence of *Photobacterium eurosenbergii,* which has been associated with bleached corals on the Great Barrier Reef (Thompson et al. 2005), in DIS and ^{H}DIS groups, but not in the HEA group.

Although the pooled analysis shows differences among the three groups, there is inconsistency among individual samples within groups (Fig. 2). For example, in the DIS group, three samples were dominated by *V. harveyi*, and three by *V. fortis*. *V. brasiliensis* and *V. chagasii* were each only present in one out of six DIS samples. ^{H}DIS samples showed slightly more consistency, with four dominated *V. fortis*, and one by *V. harveyi*. *P. eurosenbergii* was present in all but one of the DIS and ^{H}DIS samples. The HEA group showed more consistency, each with *V. fortis* dominating. This suggests healthy corals have a more stable *Vibrio* community that subsequently becomes unstable and variable during CYBD infection.

Despite variability in their constituents and proportions, the *Vibrio* communities in healthy and diseased portions of the same coral colonies show a consistent difference from one another. Colonies in which disease lesions were dominated by *V. harveyi* had a higher proportion of *V. fortis* in the healthy portions. Conversely, colonies with more *V. fortis* in the CYBD lesions had a higher proportion of *V. harveyi* in the healthy portions. Thus, the only common difference between healthy and diseased portions within a colony is that relative proportions of *Vibrio* taxa have changed. Thus, a disruption of the *Vibrio* community is always associated with the disease, but the magnitude and direction of this disruption is not consistent.

Previous studies on CYBD have suggested a specific group of *Vibrio* isolates not found in healthy corals are the causative agents of CYBD (Cervino et al. 2004a, b). However, our study did not find any *Vibrios* that are always present in CYBD lesions and always absent from healthy samples. Instead, we show that there is considerable variation in the community of *Vibrios* associated with the disease. A study of bacterial communities associated with white plague has shown similar variability, and has suggested there may be several different potential pathogens (Pantos et. al 2003). Our results suggest a variety of bacteria may be able to induce disease symptoms, and that the mechanism of disease may be a toxin that is widespread among *Vibrios*, such as haemolysins (Wang et al. 2007).

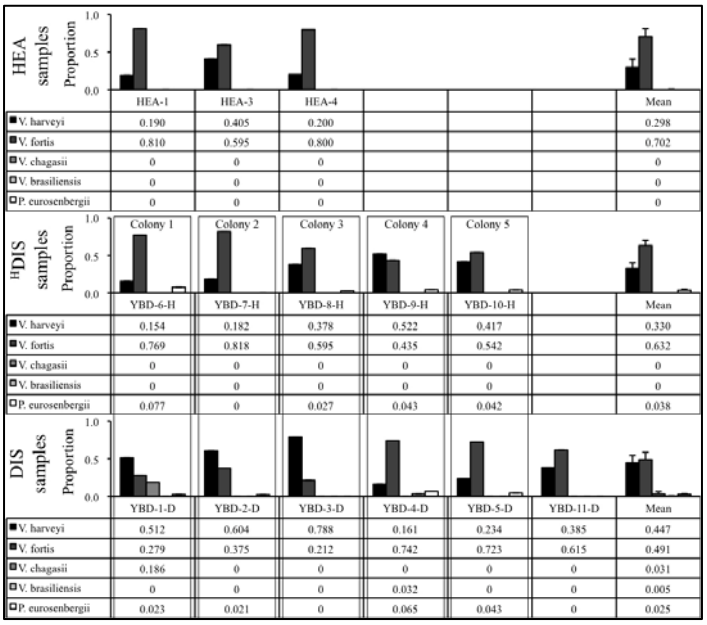

Figure 2. Relative proportions of major *Vibrio* taxa in each sample within groups (HEA (n=3), ^{H}DIS (n=5), and DIS (n=6)). Means represent the average proportion of each *Vibrio* taxon in all samples within each group, and error bars represent standard error of the mean. Rectangles surround samples from ^{H}DIS and DIS groups that originated from the same coral colony. Note that only 3 entirely healthy colonies resulted in the successful 16S sequencing of cultured *Vibrios*. Results in this figure include the individual *M. franksii* YBD sample,

The variation in the *Vibrio* community associated with CYBD may also suggest that *Vibrio* taxa are working together as pathogens, and may do so regardless of their relative proportions. Supporting this is the fact that relatedness among bacteria leads to an increase in virulence (Foster 2005). Also lending support to this theory is the fact that in the CYBD infection experiments conducted by Cervino et al. (2004b), disease symptoms were only induced when multiple *Vibrio* strains were inoculated as a group. Understanding the dynamics that may cause disease symptoms, especially by groups of opportunistic microbes, will be an important new area of research. The identification of opportunistic pathogens requires establish-

ing both pathogenicity and the conditions which facilitate opportunistic colonization. Future studies should include quantitative studies of bacterial abundance by methods such as Real Time PCR technology, pathogenicity exposure experiments and development of novel tools to diagnose pathogenic strains of CYBD.

Abstract. Coral diseases are significantly contributing to the degradation of tropical coral reefs throughout the world. A majority of research on coral diseases conducted to date has focused on microbiological and ecological surveys to characterize coral associated microbiota and factors contributing to disease prevalence. Recent studies have shown that corals use innate immunity to resist microbial invasions, but the mechanisms controlling these defenses remain poorly understood. In this study we investigated molecular responses to disease manifested by corals during periods of infection. During July of 2007 in Cayos Cochinos, Honduras, surface layer mucus samples were collected from colonies of diseased and healthy *Diploria strigosa,* putatively affected by White Plague Disease. Coral RNA was isolated from condensed mucus samples stabilized in RNA*later* (Ambion), and differential gene expression was analyzed by differential display PCR. PCR products were analyzed qualitatively by 2 % agarose gel electrophoresis, and candidate immunity genes were isolated, cloned, and sequenced. Derived sequences had similarities to immunity genes of other invertebrates, including programmed cell death. The results of this study contribute to the characterization of molecular mechanisms controlling coral immune responses to disease infection, and present the use of a novel and non-invasive method to collect coral RNA.

Keywords: Coral Disease, Immunity, Gene Expression, Differential Display PCR, Programmed Cell Death

Introduction

Since the first report of coral disease over three decades ago, research has been largely dominated by ecological and microbiological investigations (Pantos et al. 2003, Sekar et al. 2006, Santavy et al. 2001). Although these studies are necessary to characterize coral-associated microbiota and ecological factors influencing disease prevalence, it remains unclear how coral innate immune defenses contribute to disease resistance and susceptibility.

Studies of coral innate immunity are just beginning to reveal the repertoire of defenses against microbial invasions. In gorgonians, inflammatory responses involving the activation of amoebocyte differentiation and proliferation, melanin deposition, chitinases and antioxidants have been observed (Mydlarz et al. 2008, Douglas et al. 2007, Mydlarz et al. 2006). Programmed cell death pathways have also recently been identified to have a putative role in White Syndromes observed on the Great Barrier Reef (Ainsworth et al. 2007). Immunity genes that are conserved among different phyla have been identified in corals (Miller et al. 2007), but a characterization of their functions in coral innate immunity has not been reported.

The coral surface mucus layer (SML) is an important component of the coral innate immune system. It is a physical barrier that is the first line of defense against potential pathogens in the water column (Sutherland et al. 2004). Periodic sloughing of the SML and the production of antimicrobial compounds are important mechanisms for regulating coral-associated microbial communities (Brown and Bythell 2005). Differential antimicrobial properties and microbial communities of the SML of diseased and healthy corals have been observed (Gil-Agudelo et al. 2006, Ritchie 2006, Pantos et al. 2003).

In this paper, we present an investigation of differential gene expression between colonies of *Diploria strigosa* which are healthy and which are putatively infected with White Plague using coral cells sampled from SML.

Materials and Methods

Field sample collection

A survey of coral disease prevalence was conducted on a shallow patch reef area of the Plantation Beach

Reef of Cayos Cochinos, Honduras (Fig. 1). Three *Diploria strigosa* colonies putatively affected by White Plague and three apparently healthy colonies were selected for sampling between 0400 and 0500 hours before civil dawn (Table 1). Samples from the SML of diseased colonies were collected from areas adjacent to the disease lesion and apparently healthy tissue at least 20 cm from disease lesion. Mucus samples were collected from central areas of healthy colonies unaffected by disease.

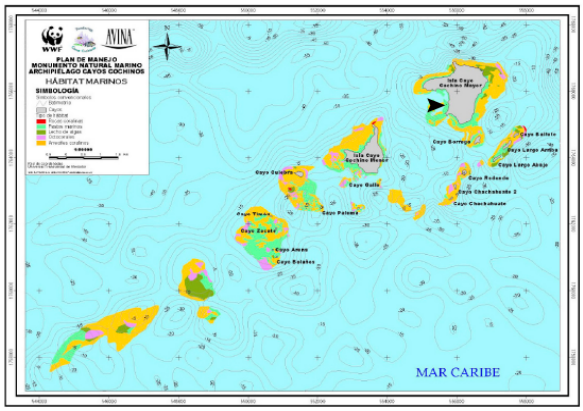

Figure 1: Map of Cayos Cochinos, Honduras. The black arrow indicates the Plantation Beach Reef area, where coral mucus samples were collected for this study (HCRF/WWF 2004).

Excess mucus production was induced at the sampling sites of the coral colonies by rapidly ejecting seawater from sterile 10 cc syringes with no needles 2 to 3 cm from coral surface. Duplicate 10 ml mucus samples were collected with sterile syringes from each sampling area. Samples were kept at ambient seawater temperature (~27°C) for no more than an hour, stored on ice, and processed upon return to shore.

Mucus samples were condensed using a hand crank centrifuge (~300 rpm) for approximately 5 min, and the resulting pellets were removed to 1.5 ml microcentrifuge tubes and stabilized in 10x volumes of RNA*later* (Ambion). Stabilized samples were stored in a conventional freezer for up to three weeks, transported at room temperature for 24 hours, and stored at -80°C until molecular analyses were performed at the laboratory in Sarasota, Florida.

RNA isolation and cDNA synthesis

Stabilized mucus samples were centrifuged (10,000*g*) for 20 min at 4°C, the RNA*later* supernatant was removed, and the resulting mucus pellets were individually homogenized in Trizol (Invitrogen). Contaminating polysaccharides, proteins and genomic DNA were removed by centrifugation (10,000*g*) for 10 min at 4°C. Total RNA was extracted from the Trizol-mucus homogenate supernatant, according to the manufacturer's protocols. One µl glycogen (1 mg l^{-1}) was added to enhance the precipitation of low concentrations of RNA with 99.5% isopropyl alcohol.

Sample #	Colony #	Condition	Area of Sample Collection

18	4	WP	Disease Front
22	4	WP	Healthy Tissue
23	A	ND	Healthy Tissue
25	B	ND	Healthy Tissue
28	C	ND	Healthy Tissue

Table 1: Description of mucus samples collected from *D. strigosa* and analyzed in this study (WP = white plague-like disease, ND = not diseased). Matching numbers under the colony column indicate samples collected from the same *D. strigosa* colony.

For each total RNA sample, four separate SuperScript III reverse transcriptase reactions (Invitrogen) were performed with one of the following primers: anchored-dT primers with HindIII restriction sites (5'AAGCTTTTTTTTTTT-N-3'; N = A, G, or C) and a mixture of random hexamer primers (Invotrogen). A negative control reaction with random hexamer primers and total RNA was conducted without the addition of reverse transcriptase, and the products of this reaction were used in coral gene-specific RT-PCR to ensure that there was a negligible level of genomic DNA contamination in the RNA samples (methods described below).

Coral gene-specific RT-PCR

Random hexamer primed cDNA was used as a template for coral gene-specific reverse transcriptase PCR (RT-PCR). PCR primers specific to cytochrome-B (Cyt-B) and β-tubulin (Tub) genes were designed from sequences available for *Manicina areolata* and *Diploria labyrinthiformis* (Accession # AB117305.1 and AB118249.1, respectively), which have sequences highly conserved with *D. strigosa*. RT-PCR was conducted to confirm the presence of coral RNA sequences in the mucus samples, which were likely to be dominated by microbial sequences. Tub and Cyt-B amplicons were sequenced to ensure these genes can be used effectively to confirm the presence

of good quality coral gene sequences in the mucus samples.

Differential display PCR
Anchored-dT primed cDNA was used as a template for differential display PCR (DD-PCR), modified from the methods first presented by Liang and Pardee (1992). Five combinations of arbitrary 13-base primers with Hind-III restriction sequences and the anchored-dT primer used to synthesize the cDNA template were used to amplify a subset of the transciptome present in each cDNA sample. DD-PCR products from samples originating from disease lesions, healthy areas of diseased colonies and healthy colony controls were separated side-by-side by 2% agarose gel electrophoresis for each primer combination. Gels were stained with ethidium bromide and DNA bands that were differentially amplified were excised for cloning and sequencing.

Sequencing candidate molecular responses to disease
Excised bands were extracted from the agarose gel using Wizard SV Gel and PCR Clean-Up System according to the manufacturer's protocols (Promega). The extracted DNA was cloned into a TOPO TA plasmid and transformed into *Escherichia coli* (strain DH5α-T1^{R}) with an Invitrogen kit for sequencing, according to the manufacturer's protocols. Plasmids were extracted from cultures of individual transformed *E. coli* colonies using Quick Plasmid Miniprep kit (Invitrogen), and the cloned DD-PCR inserts were sequenced using a standard automated Sanger sequencing protocol. Similarities of the derived sequences in this study to sequences available in the National Center for Biotechnology Information were found using a basic local alignment search tool (BLAST).

Results

Coral gene-specific RT-PCR
Unlike the results reported by Santiago-Vazquez and colleagues (2006), we were able to store coral nucleic acids successfully using RNAlater. Eight of nine samples analyzed in this study provided consistent positive results for the presence of coral nucleic acids, confirmed by the amplification of both Cytochrome-B and Tubulin genes (Table 2 and Figure 1). Amplicons were not observed for negative control reactions conducted with total RNA templates exposed to reverse transcriptase reaction conditions.

Sample #	Cyt-B	Tub
7	+	+
9	+	+
13	-	+
15	+	+
18	+	+
22	+	+
23	+	+
25	+	+
28	+	+

Table 2: Summary of results from coral gene-specific RT-PCR. Respectively, (+) and (-) indicate successful and unsuccessful amplification of coral Cytochrome-B (Cyt-B) and β-Tubulin (Tub) genes. Sample # refers to the original mucus sample from which the cDNA template originated.

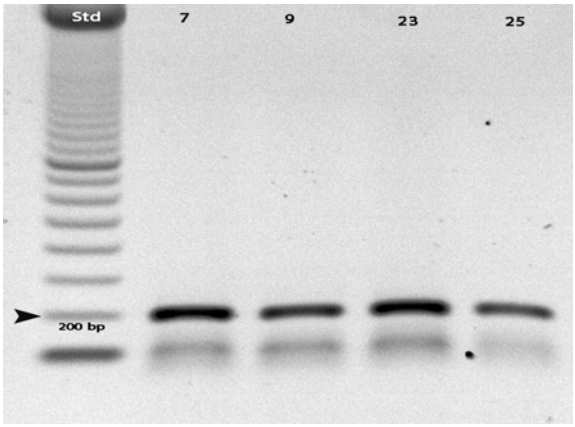

Figure 1: 1% agarose gel electrophoresis of Tubulin gene-specific RT-PCR products. "Std" lane is a 100 bp standard, and the Tub amplicons for samples 7, 9, 23, and 25 are in the expected size range of 200 bp.

Differential display PCR
A total of twenty eight differentially displayed bands were observed and excised from samples originating from diseased coral colonies (Figure 2).

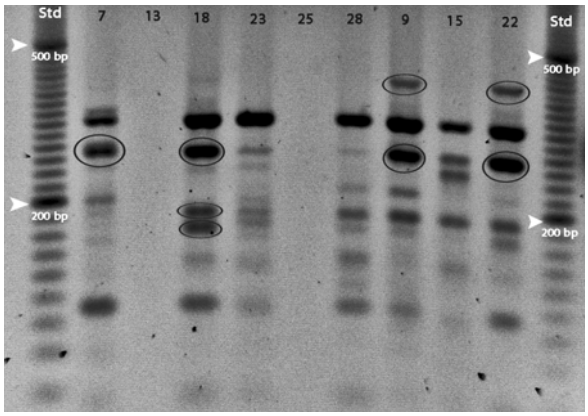

Figure 2: 2% agarose gel electrophoresis of DD-PCR products. Circled bands were excised for sequencing. Lanes "std" are standard 20 bp ladders, with white arrows indicating the 200 and 500 bp markers. The numbered lanes indicate the mucus samples from which the DD-PCR products were amplified.

Sequencing – programmed cell death gene detected at lesion boundary of White Plague-diseased corals

Sequences derived from the Cyt-B and Tub amplicons significantly matched ($E = 3e^{-30}$) sequences available for *D. strigosa* in NCBI. Sequences derived from differentially displayed bands amplified from a samples 7 and 18, originating from the lesion boundary of diseased colonies of *D. strigosa*, significantly matched ($E = 6e^{-9}$) a death domain sequence of *Nematostella vectensis* (Accession # XM 001639015.1).

Discussion

Coral innate immunity is not well understood, and to date, few molecular studies have been conducted to elucidate coral immune responses to disease (see Vollmer and Kline 2008 for a recent study). In this paper, results from a preliminary study on coral molecular responses to disease are discussed.

Most molecular analyses conducted on corals to date used invasive methods of collecting nucleic acids. These methods include the collection of entire coral colonies, large fragments or core samples that can reduce coral defenses on reefs that are already degraded (Edge et al. 2005, Smith-Keune and Dove 2007, Klueter *et al* 2006). The isolation of coral nucleic acids from condensed coral mucus is a novel method that can be used for PCR-based molecular analyses. The cellular sources of coral nucleic acids in the surface mucus layer of corals were not investigated in this study. However, mucocytes and nematocysts may release coral RNA and DNA into the surface mucus layer when the epidermis is stimulated. Amoebocytes, which are immunity-related motile cells that migrate throughout coral tissue (Meszaros and Bigger 1999), may also be shed into the mucus layer when physical irritation to the coral surface is applied.

Genomic DNA can compete with cDNA in PCR during primer annealing steps, and contamination of RNA samples with genomic DNA can significantly reduce the efficiency of DD-PCR to identify putative differentially expressed genes (Liang and Pardee 1995). Results from the negative control coral gene-specific RT-PCR reactions conducted in this study indicate a level of genomic DNA contamination undetectable by ethidium bromide staining. For that reason, an additional DNA digestion step was not performed, which would otherwise reduce the RNA concentration by a second precipitation step before cDNA synthesis.

The presence of Tub amplicons (200 bp) in all of the β-tubulin-specific RT-PCR reactions indicated that coral nucleic acids were present in each sample. However, a Cyt-B amplicon (500 bp) was not present for sample 13, which suggests that the sequence was degraded to a length significantly shorter than 500 bp. The collection of replicate mucus samples can ensure that at least one sample will have sufficient quality for DD-PCR. Variable intensity of DNA bands of the same base pair length in Figures 1 and 2 may show variable concentrations of coral RNA present in the samples. The number of coral cells and concentration of RNA excreted into the mucus may differ between diseased and healthy corals, and were unknown in this study. The starting concentration of total RNA used for reverse transcriptase reactions and DD-PCR can be normalized for samples from diseased and healthy corals, if an average concentration of coral RNA excreted into the mucus is determined by quantitative PCR amplification of the Cyt-B and Tub house-keeping genes.

Twenty eight differentially amplified bands were excised from DD-PCR products in this study. The sequencing of these amplicons is still underway, but preliminary results from the analysis of five candidate immunity genes have provided significant data upon which future investigations will be conducted. BLAST searches revealed sequence similarities of differentially amplified bands from samples 7 and 18 to a death domain sequence in *Nematostella vectensis*. Both of these samples were collected from the lesion boundary of *D. strigosa* colonies affected by putative White Plague infections.

Death domains are genes translated into conserved proteins that have functions in programmed cell death pathways (PCD) (Stehlik 2007). PCD has been investigated for its roles in mediating the destruction of cells in immune-compromised organisms, and it is activated by receptors such as Toll and Toll-like receptors (TLRs), which recognize conserved microbial ligands (Govind 2008, Ameisen 2002).

Gene sequences for TLRs have been identified in *Acropora millepora* and *N. vectensis* (Miller et al. 2007), and a recent study by Ainsworth and colleagues (2007) confirmed the presence of PCD in coral tissues adjacent to lesions characteristic of white syndromes on the Great Barrier Reef. The identification of a coral death domain as a putative immune response in *Diploria strigosa* colonies affected by putative White Plague infections suggests that PCD may have conserved functions in corals as a final line of defense against pathogenic microbial infections.

Relative role of disease and predators as drivers of decline in coral cover on the Great Barrier Reef.

I. Miller[1] and A.M. Dolman[1]

1) Australian Institute of Marine Science, PMB#3 Townsville MC, Queensland 4810

Abstract. The Australian Institute of Marine Science monitored causes of coral mortality annually on 46 reefs throughout the GBR from 1999 to 2005 and a further 46 reefs biannually from 2006. Sampling consisted of categorising corals lesions according to signs associated with coral disease, crown-of-thorns starfish and *Drupella* spp. feeding activity and lesions that could not be categorized. Of those categories recorded only increases in crown-of-thorns starfish lesions were associated with subsequent declines in coral cover. Between 1999 and 2005 there was no clear evidence to suggest that disease outbreaks had a significant impact on live coral cover on survey reefs. This result is in contrast to those recorded from the Caribbean where coral disease has lead to wholesale declines in coral cover on affected reefs. The relative proportions of diseases recorded show that lesions due to white syndrome and unknown causes make up the majority of those observed. The direct causes of a majority of coral lesions remain unexplained highlighting the difficulty of classifying coral lesions based on visual signs.

Key words: coral, disease, crown-of-thorns, lesion

Introduction

Little is known about the role disease plays in shaping the coral reef community on the Great Barrier Reef (GBR). This is despite the first disease of reef building corals being described some forty years ago (Squires 1965). Populations off hard corals in parts of the Caribbean were decimated by disease during the late 1970's and 1980's (Gladfelter 1982, McClanahan and Muthiga 1998, Aronson and Precht 1997, 2001). This has been followed by an apparent increase in disease numbers recorded on the GBR during the 1990's (McClanahan et al. 2004; Willis et al. 2004; Miller et al. 2006).

Reductions in hard coral cover on reefs have a serious impact on ecosystem function and can result in "phase shifts" where ecological services provided by the ecosystem are radically changed as the reef community is altered from one dominated by hard corals to one dominated by fleshy macro algae (Hughes 1994). Despite the events in the Caribbean and the growing recognition of the role disease plays in the ecology of Indo-Pacific hard coral species (Willis et al. 2004; Winkler et al. 2004; Raymundo et al. 2005; Dalton and Smith 2006; Page and Willis 2008) there have been few reports of disease outbreaks affecting coral cover on the GBR (e.g. Jones et al. 2004). An increase in reports of disease in other parts of the world has coincided with an increased publication rate that confounds interpretation of any patterns over time (Ward and Lafferty 2004). To help interpret the role disease plays in shaping coral communities it is important to understand background levels of disease induced mortality (i.e. the rate of unavoidable mortality that is independent of the organisms' state or behavior McNamara et al. 2004), what constitutes an increase in disease incidence above these levels and subsequently what are the impacts (Willis et al. 2004; Raymundo et al. 2005). This is increasingly important for the conservation of the GBR, already threatened by crown-of-thorns starfish outbreaks (Sweatman 2008) and other threats resulting from global warming such as coral bleaching, more frequent and intense cyclones (Hughes 2003) and increased disease (Harvell et al. 1999. The Australian Institute of Marine Science (AIMS) Long Term Monitoring Program (LTMP) has been collecting information on disease and coral cover on fixed survey sites since 1999. We examine whether observed increases in disease activity are linked to declines in coral cover on surveyed reefs between 1999 and 2005. We also compare changes in coral cover to abundance of disease and other sources of mortality on the GBR in order to determine the relative impact of identifiable diseases.

Material and Methods

Surveys of benthic organisms and SCUBA searches categorising the putative causes of coral lesions (white bare skeleton indicating recent mortality) were conducted on 46 reefs annually from 1999 to 2005 and a further 46 reefs biannually from 2006 by the

AIMS LTMP. Reefs targeted for survey were located in six latitudinal sectors over a distance of approximately 1500 km along the continental shelf. Three shelf positions were sampled (inner, mid, and outer shelf) in the four northernmost sectors, two shelf positions (mid and outer) were sampled in the Swains sector, and one (outer) was sampled in the Capricorn Bunker sector (Fig. 1).

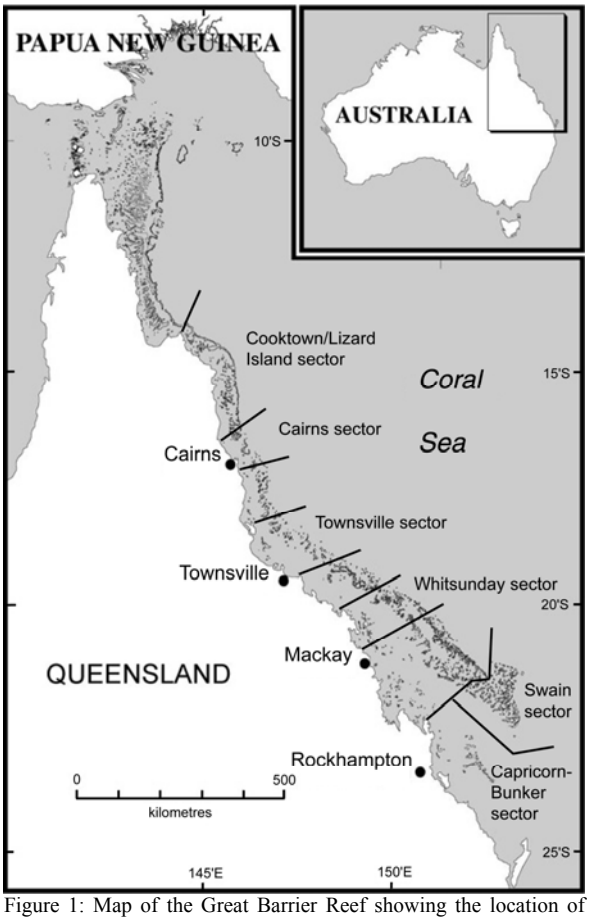

Figure 1: Map of the Great Barrier Reef showing the location of survey sectors targeted by the AIMS Long Term Monitoring Program.

At each reef, three sites positioned on the upper slope usually on the north-east flank were surveyed. Each site consisted of 5 x 50m transects along the 6-9m depth contour. Transects were marked with star pickets at the start and end, with steel rods at 10m intervals. Fibreglass measuring tapes attached to the pickets and rods allowed the same belt transect to be sampled in consecutive years.

A video recorder or still camera was used to record a 30cm wide strip along the edge of the measuring tape on each transect. Percent cover of hard corals was then estimated from the footage using a point-sampling technique. Images were captured from forty regularly-spaced frames of the video/still footage for each transect. Five systematically-distributed points were overlaid on each image and the identification of the benthic organism under each point was recorded. This provides a sample of 3000 points per reef. Hard and soft corals are identified to the highest taxonomic resolution possible, usually genus for hard coral and family for soft coral (see Abdo et al. 2004).

Causes of coral mortality were recorded using SCUBA searches conducted on a two-meter wide belt along each transect (search area $100m^2$). The observer recorded the number of individual lesions and ascribed their likely cause based on signs. These broadly fall into four major categories; disease including white syndrome (WS), black band disease (BBD), brown band disease (BrB), skeletal eroding band disease (SEB) and atramentous necrosis (AN); crown-of-thorns-starfish (COTS) ; *Drupella* spp. ; and unknown causes (see Miller 2004).

In 2006 a suite of 56 reefs (10 in common) were sampled using these methods as part of a separate research program (see Sweatman et al. 2008). The 46 LTMP reefs were again surveyed in 2007 but the time between surveys (2 years) meant that information collected in 2006 and 2007 could not be included in the statistical analysis as the model requires data collected in consecutive years. However, to determine the current relative frequency of disease types on the GBR a breakdown of the average number off disease lesions attributable to each of the categories recorded on all reefs over the period 2005 and 2007 was calculated.

To explore the relationship between changes in coral cover and coral lesion abundance a General-Linear-Model was used with log transformed coral cover as the response variable, log coral cover in the previous year as the main predictor and incidence of diseases as covariates. In log-space this kind of regression model is equivalent to the Gompertz growth model, a deterministic model frequently used to describe density-dependent population growth in discrete-time (Reddingius 1971; Dennis and Taper 1994). The intercept of the regression model estimates the log of the intrinsic growth rate, the coefficient of the population in the previous time period gives the strength of density dependence, and the coefficients of the covariates are modifiers of the growth rate and estimate the log of the proportional impact they have on population size.

Covariates (impacts) tested included the average number of lesions recorded between 1999 and 2005 for each of disease (pooled); *Drupella* spp.; COTS; and unknown causes. Covariates were square root transformed prior to analysis. All data were entered into an initial regression model with all covariates. Standardized residuals values were plotted against number of lesions due to COTS, unknown causes, disease and *Drupella* spp.. Outliers were identified

and removed for reefs where severe COTS outbreaks had decimated coral cover in the previous year, and where observed declines were due to mass coral bleaching in 1998 and cyclone damage on Low Isles reef also in 1998. A backward stepwise variable selection procedure was then used to test the importance of covariates. Covariates with the smallest partial correlation with the dependent variable were sequentially removed until all remaining covariates failed the removal criteria (probability of F-to-remove >= 0.10).

Results

Covariates for unknown causes, disease and *Drupella* spp. were all eliminated by the backward stepwise regression modeling procedure (Table 1) indicating that there was no significant association ($p > 0.10$) between coral cover in the subsequent year and lesions caused by these agents. There was, however a significant negative relationship between coral cover in subsequent years and increased COTS lesion abundance. COTS lesions were retained as a covariate in the final model (Table 2).

Covariate removed	Df1	Df2	Change in F	p (F)
Disease lesions	1	260	0.010	0.921
Drupella spp. lesions	1	261	1.256	0.263
Unclassified lesions	1	262	0.953	0.330

Table 1: Covariates eliminated during backward stepwise regression procedure and their corresponding changes in F-statistic

Covariate	Estimate	Std. error	t	P
Constant	0.224	0.073	3.09	0.002
Initial cover	0.939	0.021	44.1	<0.001
COTS lesions	-0.206	0.018	-11.6	<0.001

Table 2: Final regression model resulting from backwards stepwise regression procedure. The constant estimates the log of the intrinsic growth rate and the initial cover parameter estimates the strength of density dependence. Together they define the equilibrium coral cover [exp (0.224 / (1-0.939) = 39.3%]. The COTS lesions parameter estimates the proportional impact on next year's coral cover of COTS outbreaks that result in √x observed COTS lesions [exp (-0.206) = 0.81].

The majority of lesions recorded on fixed transects between 2005 and 2007 could not be assigned a cause (Fig. 2). White syndrome and *Drupella* spp. lesions were the most commonly assigned while lesions due to black band disease and atramentous necrosis were the least assigned. Only a small proportion (6.3 ± 1%) of the lesions observed could be attributed to COTS, which were on average less common than lesions due to *Drupella* spp., WS or SEB. There was some regional variation in the prevalence of lesion types. While unknown lesions dominate the counts in the majority of sectors WS was particularly common in the Capricorn Bunker sector. SEB was most common on northern reefs in the Cooktown Lizard Island sector while BrB was highest in the Pompey sector. BBD and AN were all observed at very low levels in the majority of sectors surveyed.

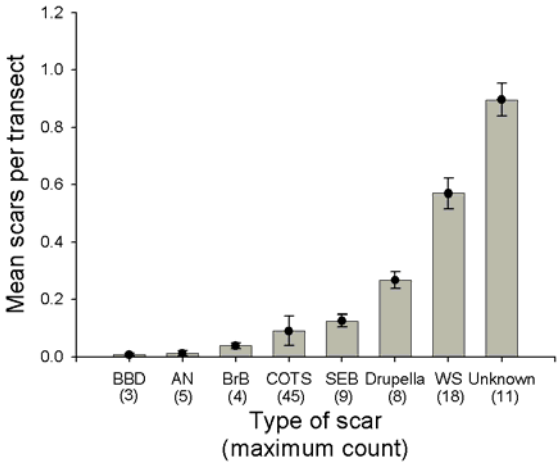

Figure 2: Abundance (mean ± SE) of different coral lesion types recorded per transect during AIMS scuba search surveys on fixed sites recorded from 2005-2007.

Discussion

The major finding of this study was the absence of a relationship between coral cover and the abundance of disease lesions on reefs of the GBR. In fact of all the factors tested only increases in lesion abundance due to COTS predation was positively associated with subsequent declines in coral cover. The latter result is not surprising as COTS have long been known to be a major source of coral mortality since outbreaks were first indentified in the 1960's (Birkeland and Lucas 1990). On the GBR three series of COTS outbreaks have caused declines in coral cover that have dwarfed losses from other disturbances such as storms or coral bleaching recorded over the same period (Sweatman et al. 2000). That there is no clear relationship between abundance of disease lesions and subsequent changes in coral cover on the GBR is in direct contrast to many other studies, particularly those in the Caribbean. In the Caribbean the most abundant reef building corals (*Acropora* spp.), were decimated by epizootics during the 1970's and early 1980's (Gladfelter 1982, McClanahan and Muthiga 1998, Aronson and Precht 1997). Since then coral cover on many reefs in the region has continued to decline with more epizootics recorded in recent times (Porter et al 2001, Patterson et al. 2002). While epizootics have been recorded from the GBR (Jones et al. 2004) they are rare. In fact reports of disease from the Indo-

Pacific, in general make up a much smaller proportion of reports when compared to those from the Caribbean (Willis et. al. 2004). This is despite the fact that the Indo-Pacific region is home to more than 80% of the reefs worldwide (Bryant et al. 1998). A possible explanation for the GBR is that coral diseases in this region are less virulent than in the Caribbean. Over the period 1977 to 2002 Gardner et al. (2003) reported a region-wide decline in hard coral cover in the Caribbean basin of 80% with coral disease playing a key role in this decline. Conversely declines in coral cover on the GBR over the last two decades have been generally driven by factors other than disease and where declines in some regions have been recorded they have been balanced by increases in others (Sweatman et al. 2008). In the Caribbean coral disease can have devastating affects on coral populations even when coral cover is low. For instance between 1996 and 1999 losses of *Acropora palmata* in the Florida Keys national Marine Sanctuary averaged 87% or greater from an already low (12% on average) cover (Sutherland 2004). In contrast on the GBR coral cover needs to be over 50% before outbreaks of white syndrome can occur (Bruno et. al 2007).

Another explanation for the observed result is that extrinsic factors may be differentially driving increases in the prevalence of coral disease in the Caribbean compared to those recorded from the GBR. However while many studies have pointed to rising disease prevalence (Ben-Haim and Rosenberg 2002, Sutherland et al. 2004, Weil et al. 2006), other studies have not always supported these conclusions (Voss and Richardson 2006) and a lack of baseline studies makes any interpretation of recent trends difficult (Ward and Lafferty 2004).

A third possible explanation is that lesions have been recorded at a level where they play a limited role driving observed changes in coral cover and that disease induced mortality on the GBR is simply outweighed by growth and renewal i.e. "background" levels of coral mortality (McNamara et al. 2004).

Previous studies have highlighted the increasing number of hard coral disease recognized on the GBR (Willis et al. 2004). Surveys by the AIMS LTMP in recent years have endeavored to include emerging diseases once signs for their identification have been confirmed. As a result the LTMP provides a clear picture of the ubiquity of coral disease on the GBR. Coral diseases appear widespread on the GBR with lesions caused by WS and SEB generally more frequent than those encountered for either *Drupella* spp. or COTS. This highlights that coral mortality due to disease, in particular SEB and WS, is a common occurrence on the GBR. All five disease types recorded by the LTMP have been generally found throughout the GBR system (AIMS data) though BBD, BrB and AN remain relatively rare. White syndrome is the most commonly encountered disease on the GBR. This is in contrast to other research that shows SEB to be generally more common than other diseases (Page and Willis 2008). The reason(s) for the apparently different results are unclear. Both WS and SEB have been well described with a known cause (Sussman et al. 2008, Antonius 1999). A possible explanation is that the divergent results are at least partially due to differences in sampling technique (i.e. observers, different locations on the reef surveyed, different survey methods including search area and time). Furthermore the most abundant lesion category recorded during this study was for those that remain unidentified. This highlights the difficulty of identifying signs of disease in the field. The problems of characterizing a disease (Richardson 1998) and then using the external appearance of corals for diagnosis is well recognized (Ainsworth et al. 2007a). The AIMS LTMP overcomes this problem by having a clear methodology (Miller 2004).

In terms of future scenarios for coral epizootics on the GBR indentifying disease and understanding disease dynamics, including trends in disease occurrence, is fundamental to conserving ecosystems faced with rising anthropogenic stresses (Ward and Lafferty 2004). This is particularly true given the relatively pristine nature of the GBR and that it is already under threat from COTS (Sweatman 2008), coral bleaching (Berkelmans et. al. 2004) and increased frequency and intensity of cyclones (Hughes 2003). The need to identify disease in the field and understand its role in the reef community can only become more important as increases in water temperatures (Jones et al. 2004, Bruno et al. 2007, Bourne 2008), nutrients (Bruno et al. 2003, Voss and Richardson 2006) bleaching (Muller et al. 2008) and in some cases, interactions with other organisms (Nugues et al. 2004, Aeby 2007, Nugues and Bak 2009) may be expected lead to increased prevalence of disease on the GBR in future years.

Acknowledgement

The authors would like to thank the current and past members of the AIMS LTMP; D. Abdo, D. Bass, S. Burgess, A. Cheal, J. Davidson, G. Coleman, M. Emslie, K. Johns, M. Jonker, A. McDonald, S. Neale, K. Osborne, W. Oxley, C. Page, H. Sweatman and A. Thompson for collecting the data. We would also like to thank the volunteers that have put up with the vagaries of field trips on the GBR and the captains and crew of the RV Harry Messel, RV Cape Ferguson and RV Lady Basten for support in the field.

Significance of immune responses in *Diadema antillarum* to Caribbean-wide mass mortality

G. Beck[1], R. Miller[2], J. Ebersole[1]

1) Univ. of Massachusetts – Boston, Biology Department, 100 Morrissey Blvd., Boston, MA 02125
2) Marine Science Institute, University of California – Santa Barbara, Santa Barbara, CA 93106

Abstract. Mass mortality of the grazer *Diadema antillarum*, probably caused by a water-borne pathogen, was a major factor leading to algal domination of Caribbean reefs. Recovery of *Diadema* in St. Croix allows us to addresses questions on how recovery may be influenced by immunological processes. What are the basic features of immunological responses in *Diadema*? How does strength of immune responses in *Diadema* compare to other urchins that did not die (*e.g., E. lucunter*, or *E. viridis*)? We used coelomic fluid and coelomocytes of urchins from several locations on St. Croix to test their immune responses. All urchins released humoral defense molecules when stimulated by various agents – with one exception. *Diadema* did not respond as efficiently as other urchins did to lipopolysaccharide. This suggests a defect in immune response that is specific to *Diadema* and independent of stressors associated with particular environments. These studies may provide information required to understand whether a weakened immune response was responsible for the mass mortality, and whether strengthening of immunity has occurred since. Effective management of a recovery may depend on knowing whether diseases continue to impact *Diadema* population growth due to weak immune responses, and whether a recovered/restored population could experience another die-off.

Introduction

The Black-spined Sea Urchin and Coral Reef Ecology

In 1983 the black-spined sea urchin (*Diadema antillarum*) began to vanish from the Caribbean Sea, disappearing first from coral reefs close to the Panama Canal and eventually from almost every coral reef in the Caribbean by 1984. This mass mortality, which wiped out more than 97% of the Caribbean-wide *Diadema* population, was one of the most devastating mortalities ever recorded for a marine animal. This die-off is a major factor leading to a phase shift from coral-dominated to algae-dominated communities that has occurred on many Caribbean reefs during the past 20 years (Lessios 1988; Hughes 1994). In St. Croix, the density of *Diadema* before the 1983 die-off was estimated to be ≈6.4 individuals/m^2. In 1984, densities plummeted to <0.1 individuals/m^2, and in 2001 there were ≈0.17 individuals/m^2 (Lessios 1988). Decades after the mass mortality event, *Diadema* was still rare, with very low recruitment rates (Lessios 1988; Edmunds and Carpenter 2001).

It is thought that the demise of *Diadema* was caused by a water-borne pathogen. Indeed, plots of surface currents in the Caribbean Sea coincide significantly with the spread of the *Diadema* die-off (Lessios 1988; Miller et al. 2003). In addition, several species of bacteria capable of killing *Diadema* have been associated with dying urchins in the laboratory, but bacteria have not been detected in field-collected individuals (Bauer and Agerter 1987).

Recent recovery of *Diadema* has been associated with reductions in algal cover and increased coral recruitment success in Jamaica (Edmunds and Carpenter 2001), and with reductions in algal cover in St. Croix (Miller et al. 2003), where *Acropora palmata* colonies are reappearing in areas with high *Diadema* densities, but are largely absent where *Diadema* are absent or uncommon (unpublished). Recovery of *Diadema* may be critical to restoration of coral communities, particularly where reefs have few herbivorous fishes due to heavy fishing (Hay 1984), as in the USVI (Garrison et al. 1998). Many factors may be influencing *Diadema* recovery, including predation, competition from other herbivores, and effects of rarity [low reproduction and recruitment stemming from low population density (*e.g.,* Lessios 1988; Miller et al. 2003)]. Another factor that must be considered is possible immunological weakness of this *Diadema* population which would allow continuing morbidity or mortality due to the original mass mortality pathogen or other diseases. Continuing recovery of *Diadema* populations in St. Croix (Miller et al. 2003) has allowed study of how recovery dynamics of *Diadema* may be influenced by basic

immunological and ecological processes.

Our studies are aimed at uncovering basic features of the immunological responses of *Diadema*: What are the basic features of the immunological responses of *Diadema*? How does strength of immune responses in *Diadema* compare to other Caribbean urchins that did not die off (*e.g., Tripneustes ventricosa, Echinometra lucunter,* or *Echinometra viridis*)? Are there immunological differences in local populations of *Diadema* on St. Croix that could be related to site-specific speeds of recovery?

Invertebrate Immunity

Animals posses both cellular and secreted protein (humoral) mechanisms for distinguishing self from non-self. Potential invaders include viruses, bacteria, protozoa, fungi and even protein molecules. The distinction between "self" and "nonself" is achieved by even the most primitive protozoans (Beck and Habicht 1996; Flajnik and DuPasquier 2004). Evolutionary forces have given rise to two arms of the immune system in animals: acquired (also known as adaptive or specific) and innate (or non-specific) immunity. Acquired immunity is only found in vertebrates. Invertebrates have innate immune systems, characterized by activation of immune effector cells, mediation by circulating coelomocytes. Invertebrates have many of the innate host defense mechanisms vertebrates do, but lack the specificity of the vertebrate immune response. The position in phylogeny of echinoderms makes them an important invertebrate group for comparative studies, including those addressing the evolution of the immune system. Although echinoderms efficiently clear bacteria from the coelomic fluid (CF) and mount an innate type immune response to pathogens and their products by coelomic fluid cells (coelomocytes), little is understood of the molecular mechanisms and genes that are used by these cells in response to a non-self challenge.

Phagocytosis [the engulfment of foreign material (*i.e*., pathogens) by specialized cells (*i.e*., phagocytes)] is the predominant cellular defense mechanism in vertebrates and invertebrates (Beck and Habicht 1996; Flajnik and DuPasquier 2004). Humoral-based defenses include: antimicrobial peptides (AMPs) and proteins (*i.e.,* lysozyme), phenoloxidase, complement-like proteins (Beck and Habicht 1996; Flajnik and DuPasquier 2004; Raftos et al. 1992; Beck et al. 1996; Lin et al. 2001), and reactive oxygen intermediates [ROI; *e.g.*, superoxide ($O_2^{\cdot-}$)] (Meier 2001; Babior et al. 1973; Clifford and Repine 1984; Beck et al. 2001). The ability of invertebrates to combat infections is dependent on the release of ROI (a group of inorganic compounds that are used by phagocytes in the formation of more toxic radicals to destroy pathogens).

Materials and Methods

Reef surveys: At each back-reef site at each sampling time, SCUBA divers counted *Diadema* in 14 randomly located 50m × 2m transects, and *Diadema* test diameters were recorded as small [<40mm; mean size of 1 yr. old *Diadema* = 48.6 mm (Karlson and Levitan 1990)], medium (41-60mm) or large (>60mm).

Collection of sea urchin coelomocytes: Urchins were collected from three study sites around St. Croix and processed within 2 hrs. A syringe containing ice-cold anticoagulant solution (99.8g EDTA and 33.5 ml 2-mercaptoethanol to 1L in seawater) was inserted into the coelom through the soft tissue surrounding the urchin mouth structure (Aristotle's lantern) to extract coelomocytes (Beck and Habicht 1991). These cells were washed two times and resuspended in saline at a concentration of 1×10^6 cells/ml. Cells were counted in a hemocytometer (Lin and Beck 2007). Proteins in the CF were quantified by the Bradford assay (Beck and Habicht 1991; Lin and Beck 2007). Sodium dodecycl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) of the CF was performed as previously described (Lin et al. 2001; Beck and Habicht 1991).

Determination of reactive oxygen intermediates (ROIs): The ROIs produced by phagocytes were assayed using a spectrophotometric assay to measure $O_2^{\cdot-}$. When phagocytes engulf a pathogen, a burst in oxidative metabolism results in the generation of ROIs (Beck et al 2001; Arumugam et al. 2000; Anderson et al. 1992; Vidya et al. 2007; Bettencourt et al. 2007). A simple and direct method of detecting this metabolic change is the nitro-blue tetrazolium (NBT) reduction assay [wherein the yellowish NBT is reduced to an insoluble, purplish precipitate in the cells (Arumugam et al. 2000; Anderson et al. 1992)]. Two hundred fifty µl cells (10^6 cells/ml), 250 µl of 0.1% NBT, 10µl stimulator [*e.g.,* peptidoglycan, lipopolysaccharide in phosphate buffered saline (PBS)]) or PBS alone (control) were mixed and incubated at 22ºC. (Beck et al 2001; Arumugam et al. 2000; Anderson et al. 1992; Vidya et al. 2007; Bettencourt et al. 2007). After 1 hr the cells were separated from the supernatant by centrifugation in a microfuge, and reduced NBT in the pellet was determined spectrophotometrically at an optical density at 630 nm (in quadruplicate). The production of $O_2^{\cdot-}$ was monitored over time.

Results

Enumeration of Diadema on the Reefs of St. Croix

We asked whether the initial recovery of *Diadema* that we have observed on critically affected coral reefs of St. Croix (Miller et al. 2003) is continuing? To determine relative rates of population recovery in different parts of St. Croix, U.S.V.I., *Diadema* were counted and sized twice at each of six locations (Fig. 1): Two south shore back-reef sites (TH & RB), two north shore back-reef sites (POW & SOL), and two north shore patch reefs in Tague Bay (TB), following the methods of Miller *et al.* (Miller et al. 2003). As can be seen in Fig. 2, recovery of *Diadema* on St. Croix continues to be slow, or has stalled out entirely.

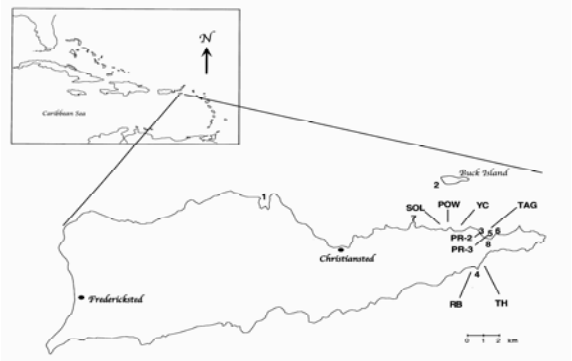

Figure 1: Map of St. Croix, USVI showing the 6 study sites. SOL = Solitude Bay, POW = Pow Point, YC = Yellowcliff Bay, TAG = Tague Bay, TH = Turner Hole, RB = Rod Bay. (From 4)

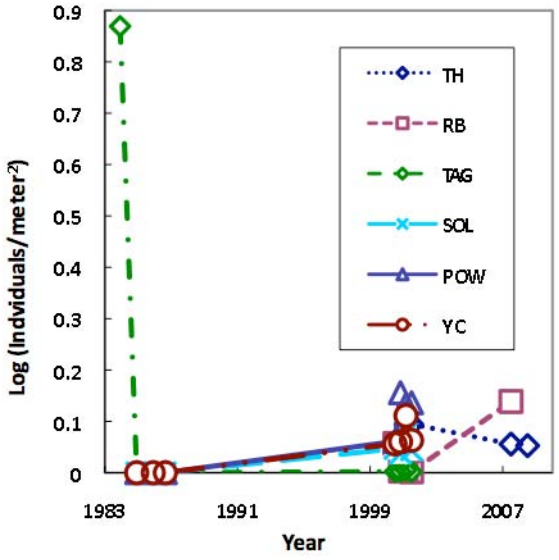

Figure 2: The number of *Diadema* found at study sites on St. Croix from 1984 to 2008. The study sites are the same as described in Fig. 1.

Gross Protein Profiles and Cellular Components of Coelomic Fluid in the Urchins

Protein profiles and cellular components of the coelomic fluid varied substantially among the four urchin species (Fig. 3). *Diadema* differs significantly from *Tripneustes* and the two *Echinometra* species in the counts for both red blood cells and total coelomic cells, but in both cases the values for *Diadema* are in the middle of the pack and not at either extreme. On the other hand, as determined by the Bradford assay, *Diadema* has significantly more protein in the CF than any of the other urchins.

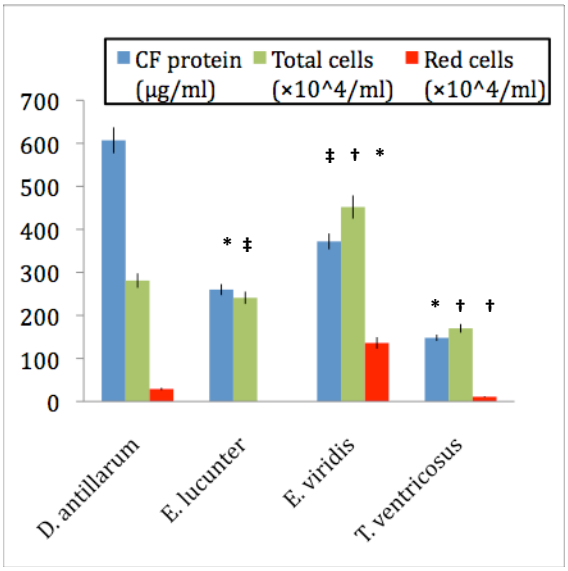

Figure 3: Analysis of CF and coelomocytes of 4 urchins found in the coastal waters of St. Croix (mean ± SD for 6 urchins of each species). **P*< 0.001 when compared to *Diadema* alone, †*P*< 0.01 when compared to *Diadema* alone, ‡*P*< 0.05 when compared to *Diadema* alone.

Differences in Protein Profiles of Coelomic Fluids of Diadema from Different Sites (SDS-PAGE)

When CF proteins from *Diadema* collected from 3 different sites on St. Croix (SOL, RB, and TH) were subjected to SDS-PAGE we could see no readily apparent differences in their crude protein profile (Fig. 4).

Changes in the Humoral Responses of the Urchins

The ability of invertebrates to combat infections depends, in large part, on the release of reactive oxygen intermediates, groups of inorganic compounds that inhibit vital enzymes of pathogens and are used by phagocytes in the formation of more toxic radicals (Arumugam et al. 2000; Anderson et al. 1992; Vidya

et al. 2007; Bettencourt et al. 2007). As seen in Fig. 5 all the urchins were capable of releasing $O_2^{\cdot-}$ when stimulated by various agents. There was one statistically significant exception: The response of *Diadema* to stimulation with lipopolysaccharide (LPS) is low compared to the other urchins. There is no geographic component to the lack of this response to LPS since *Diadema* from all sites were equally unresponsive (unpublished).

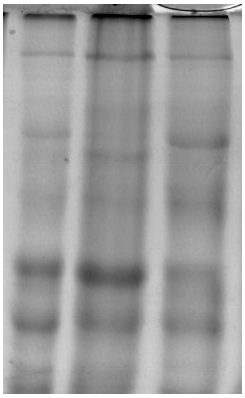

Figure 4: SDS-PAGE (7.5% SDS-PAGE gel stained with Coomassie Blue R-250) of CF from *Diadema* collected from 3 different locations on St. Croix.

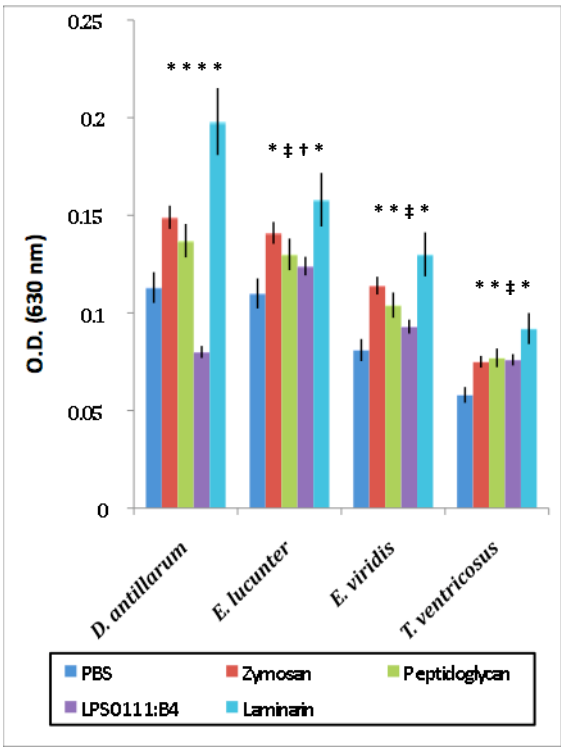

Figure 5: Stimulation of sea urchin coelomocytes with different agents. Data are presented as mean ± SD from six experiments. *P< 0.001 when compared to PBS control, †P< 0.01 when compared to PBS, ‡P< 0.05 when compared to PBS.

Conclusions

Recovery of *Diadema* on St. Croix continues to be slow, or has stalled out entirely. This recovery, with its beneficial effects on corals, is neither universal nor complete in the Caribbeanmand is progressing even more poorly in the Florida Keys (Miller et al. 2003; Carpenter and Edmunds 2006; personal observation). A principle recommendation of the recent *Diadema* Workshop, hosted by the Nature Conservancy, the National Fish and Wildlife Foundation, and the Rosenstiel School of Marine and Atmospheric Sciences in the summer of 2004, was to study key aspects of *Diadema* biology and ecology. Efforts to restore *Diadema* in the Florida Keys by seeding small areas with juvenile urchins have been unsuccessful because juveniles suffered severe mortality after they were introduced to the reefs (Rosov 2002). Efforts to reverse the algae-coral phase shift on coral reefs of the Caribbean and Florida Keys through restoration/recovery of *Diadema antillarum* can succeed only through improved comprehension of the recovery process. Managing a more rapid recovery may depend on understanding the competitive and predator/prey relationships between fishes and urchins, and how increasing adult *Diadema* densities affect recruitment and juvenile survival. It is also critical to understand whether weakened immune systems in *Diadema* were partly responsible for the mass mortality, and how much strengthening of immune systems has occurred since the die-off.

We used a preliminary broad-based "shotgun" approach (*e.g.,* coelomic fluid and coelomocyte population characterization) in an attempt to quantify any differences in host defense responses between several Caribbean sea urchin species. Our experiments suggest that the strength of the humoral immune response in *Diadema* appears to be weaker than in other urchin species of St. Croix. In addition, in both humoral assays and SDS-PAGE experiments we have observed that there are no differences among *Diadema* from different St. Croix locations. The inability of *Diadema* to respond as efficiently to LPS –a conserved structural component of gram-negative bacterial cell walls– as other urchins do could be a clue to a defect in a host defense response to a pathogen. One possible explanation for this decreased responsiveness could be a defect in Toll-like receptors (TLRs). The TLRs are a family of essential cell surface proteins of the innate immune system of vertebrates and invertebrates (Bochud et al. 2007; Akira et al. 2006; Beutler 2004). Their extracellular domains are capable of recognition of different microbial-associated molecular patterns (MAMPS). For example, TLR-4 detects LPS and mannan, while TLR-2 detects peptidoglycan and other β-glycans

(Bochud et al. 2007; Akira et al. 2006; Beutler 2004). This apparent *Diadema* lower response to LPS could be due to a defect in TLR-4 or a second polypeptide (MD-2) that binds to the extracellular domain of TLR-4 and enables it to bind to the conserved inner region of LPS. Is there a defect in LPS signaling in *Diadema* [*e.g.,* TLR-4 and/or MD-2 defects, a TLR-4/MD-2 signaling defect)? One could argue that not all *Diadema* TLRs are defective as *Diadema* responds appropriately (when compared to the other urchins) to peptidoglycan and zymosan (TLR-2 ligands) (Fig. 5).

Whatever the molecular basis for a weakened immune response in *Diadema antillarum*, the weakness could have consequences for the future of Caribbean coral reefs. The recovery dynamics of *Diadema* have been patchy in St. Croix waters, with some localities experiencing earlier, and/or more rapid recovery than others. Since *Diadema* from all parts of St. Croix seem to be showing the same degree of immunological weakness, we cannot associate local differences in recovery with local differences in immune response. Efforts to reverse the algae-coral phase shift on coral reefs of the Caribbean and Florida Keys through restoration/recovery of *Diadema* can succeed only through improved comprehension of the recovery process. It is critical to understand whether a weakened immune response in *Diadema* was responsible for the mass mortality, how much strengthening (if any) of immune systems has occurred since, whether continuing weakness may be interfering with *Diadema* recovery, and whether a recovered population could experience another epidemic. However slow, continuing recovery of Caribbean *Diadema* and the existence of populations of *Diadema antillarum* and related species that were not involved in the die-off affords an opportunity to look at how recovery and post-recovery dynamics of *Diadema* may be influenced by the development of immunological resistance.

Abstract. Coral diseases have played a major role in the degradation of coral reefs in the Caribbean, including those in the US Virgin Islands (USVI). In 2005, bleaching affected reefs throughout the Caribbean, and was especially severe on USVI reefs. Some corals began to regain their color as water temperatures cooled, but an outbreak of disease (primarily white plague) led to losses of over 60% of the total live coral cover. *Montastraea annularis*, the most abundant coral, was disproportionately affected, and decreased in relative abundance. The threatened species *Acropora palmata* bleached for the first time on record in the USVI but suffered less bleaching and less mortality from disease than *M. annularis*. *Acropora palmata* and *M. annularis* are the two most significant species in the USVI because of their structural role in the architecture of the reefs, the large size of their colonies, and their complex morphology. The future of the USVI reefs depends largely on their fate. *Acropora palmata* is more likely to recover than *M. annularis* for many reasons, including its faster growth rate, and its lower vulnerability to bleaching and disease.

Key words: disease, *Acropora palmata, Montastraea annularis*

Introduction

Coral diseases have played a major role in the degradation of coral reefs in the Caribbean, including those in the US Virgin Islands (USVI) (Weil et al. 2006, Rogers et al. 2008a). White band disease, first described from St. Croix, USVI (Gladfelter 1982), decimated *Acropora palmata* in the late 1970s and 1980s (Gladfelter 1982, Aronson and Precht 2001). Now there are many more coral diseases, and they are affecting virtually all coral species (Weil 2004). White plague has been the primary disease affecting *Montastraea annularis* and other massive corals. Although white band disease is less common now in the USVI, white pox disease and other un-described diseases are affecting *A. palmata*. In this paper we use the terms white pox and white plague based on the similarity of the gross signs observed in the field to descriptions in the scientific literature. These diseases have been associated with the pathogens *Serratia marcescens* (Patterson et al. 2002) and *Aurantimonas coralicida (*Denner et al. 2003), respectively, but these bacteria have not consistently been isolated from diseased corals at USVI (or other) study sites (Polson 2007). As Work et al. (2008) and others have noted, coral disease investigations are at a very early stage.

Although the coral reefs in the USVI have deteriorated from overfishing, runoff, hurricanes, and a number of other causes (Rogers and Beets 2001, Rogers et al. 2008a, Rothenberger et al. 2008), the greatest losses since studies began over 40 years ago have been from the combination of bleaching and disease from 2005 to 2006 (Miller et al. 2006, Muller et al. 2008, Rogers et al. 2008b). Conclusions that 18% of the world's coral reefs will likely be "lost" by 2030 (IPCC 2007) are appearing in the scientific literature. Although there is no clarification of just what is meant by the word "lost", many reefs have certainly deteriorated severely. Specifically, in the Caribbean, live coral cover has declined significantly, and primary reef-building species such as *Acropora palmata* and *Montastraea annularis* have decreased in abundance.

Here we briefly describe the recent declines in the USVI and discuss the potential for recovery of the two most significant species, *A. palmata* and *M. annularis*. *Montastraea annularis* is the most abundant coral on deeper (5 to 20 m) reefs, outside the *A. palmata* zones. These species are the main reef builders, with colonies that can reach several meters across, and with a complex morphology that provides shelter and habitat for a diversity of fish and other

organisms (Goreau 1959, Shinn 1963, Ogden and Ehrlich 1977, Lirman 1999).

Effects of bleaching and disease on deeper (5 to 20 m) reefs in the USVI

The Caribbean-wide bleaching event in 2005 and subsequent disease outbreak led to an average loss of over 50% of the living coral cover at long-term study sites in the USVI in one year and an average loss of over 60% in two years (Rogers et al. 2008b). Four of the five sites are within Marine Protected Areas [Virgin Islands National Park (St. John) and Buck Island Reef National Monument (St. Croix)]. These are being monitored by National Park Service (NPS) biologists with the South Florida Caribbean Inventory & Monitoring Network. An average of c. 96% of the total coral cover bleached, including over 90% of the *Montastraea annularis* complex. [*Montastraea annularis* complex, abbreviated as *Mac*x, refers to *M. annularis*, *M. franksi*, and *M. faveolata* (Weil and Knowlton 1994)]. Over 90% of the disease lesions and the area killed by disease occurred on *Mac*x, and the relative abundance of *Mac*x went from 79.2% to 58.6%. *Montastraea annularis* initially made up 55.6% of the coral cover but declined to 40.9% by 2007. The total coral cover on these reefs fell from an average of 21.4% to 10.3% after 1 yr and then to 8.3% after 2 yrs. Because National Park Service and US Geological Survey scientists increased the frequency of monitoring to every few months during the bleaching event and subsequent disease outbreak, it was clear that the significant coral mortality was from disease, not directly from bleaching.

Effects of bleaching and disease on *Acropora palmata* colonies

USGS biologists were monitoring individual *A. palmata* colonies during this event and observed bleaching of this species for the first time on record in the USVI. About 48% (of a subset of 467 colonies that were being monitored) bleached, 13% died partially, and only 8% died completely. Muller et al. (2008) found a positive relationship between temperature and disease in 2005, the year of the bleaching event. In addition, the average area of disease-associated mortality was significantly higher on bleached colonies, suggesting that disease severity was related to bleaching susceptibility. Although some colonies died partly or totally from bleaching and disease, this species did not suffer such extensive losses as *M. annularis* and many other species. The bleached *A. palmata* colonies around St. John had regained their normal color by January 2006. In contrast, *M. annularis* colonies at the long-term study reefs remained pale until at least October 2006.

Potential for recovery of *Acropora palmata* and *Montastraea annularis*

For a variety of reasons, *A. palmata* has a greater chance of recovering than *M. annularis*. What exactly is meant by recovery? In the strictest sense, full recovery would entail a return to the same number of colonies, overall amount of living coral cover, and genotypic diversity present at a specified time. Currently *M. annularis* is found to depths over 40 m (Armstrong et al. 2006) and in several reef zones, and is far more abundant than *Acropora palmata* which occurs typically in less than 8 m and in fewer zones. Even before the 2005/2006 bleaching and disease event, Edmunds and Elahi (2007) predicted possible extirpation of *M. annularis* at one site in St. John, based on a demographic model using data from three 10-m long transects dominated by this species.

More information is needed on the levels of sexual recruitment in both species. Both species are broadcast spawners and both spawn in late summer, a time of higher vulnerability because of hurricanes and generally warmer water. Several studies show low levels of recruitment for both species (Bak and Engel 1979, Rogers et al. 1984, Edmunds 2000). However, the genotypic diversity of *A. palmata* around St. John is quite high and is evidence that sexual recruitment is occurring here as well as elsewhere in the Caribbean (Baums et al. 2006, Rogers et al. 2008b; but see Williams et al. 2008). For example, in Haulover Bay, 43 of 48 colonies were different genotypes. Sexual recruits of *A. palmata* on dead portions of *A. palmata* colonies cannot be distinguished from surviving remnants, but around St. John many small colonies growing directly on rock substrate are further evidence of sexual recruitment. Genotypic diversity of *Mac*x is unknown in this area and certainly a confounding factor when evaluating the potential for recovery.

Although both *A. palmata* and *M. annularis* are able to reproduce asexually (Highsmith 1982, Foster et al. 2007), *A. palmata* as a branching species probably has a greater potential for dispersal through fragmentation. This species typically has more damage from storms than massive colonies (Woodley et al. 1981, Hubbard et al. 1991). The columnar or lobar morphology of *M. annularis* begins to develop when the colony is still relatively small, in some cases less than 30 cm across. Although the separate lobes can be dislodged and dispersed, fragmentation is not as likely as in *A. palmata* and the separate "fragments" are heavier and probably not often transported far from the donor colony. (Unlike *A. palmata* fragments, the lobes often separate from the colony at the base where there is coral skeleton, not

living coral.) Of course, not all *A. palmata* fragments attach and survive (Lirman 2000a, Williams et al. 2008). At Saltpond Bay, on the south side of St. John, 60% of the (naturally-generated) fragments survived for three or more months (USGS, unpublished data).

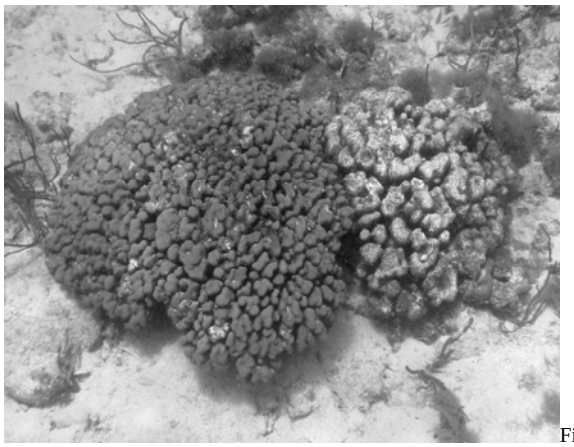
A few recent studies use analysis of genotypes to document dispersal of clones. Baums et al. (2006) showed that *A. palmata* fragments from one genet had dispersed over a distance of more than 70 m on one Florida reef. Foster et al. (2007) reported dispersal of *M. annularis* lobes (columns) up to 9 m away on Honduras reefs affected by storms, but the clonality was lower than reported for many *A. palmata* populations (Baums et al. 2006).

The scientific literature has few studies of growth rates of corals from different locations. However, in the USVI *A. palmata* has much higher growth rates (about 5 to 10 cm per year, Gladfelter et al. 1978) than *M. annularis* (less than 1 cm per year, Gladfelter et al. 1978, Hubbard and Scaturo 1985).

Healing rates of *A. palmata* after physical damage, for example from storms, and regeneration of disease lesions can be quite rapid (Rogers et al. 1982, Lirman 2000b, Muller 2007). Less is known about the ability for lesions on *M. annularis* to regenerate, and the nature of the damage to this species differs in that colonies are often abraded by sand or dislodged from their bases rather than fractured. The cause of the lesions can make a difference in the coral's ability to regenerate tissue or tissue and skeleton. Meesters et al. (1994) noted that experimentally-created lesions on *M. annularis* usually did not completely close, leaving bare space for colonization by algae and other organisms. Bak et al. (1977) showed repair of small, experimentally-created lesions on *M. annularis* over several days. Bak (1983) showed that regeneration of small, artificially-created lesions was more rapid in *A. palmata* than in *M. annularis*.

Montastraea annularis currently appears more vulnerable to diseases than *A. palmata*. Although almost 90% of the *A. palmata* colonies in studies around St. John had disease (primarily white pox) when observed in monthly surveys, many of these lesions healed. In contrast, growth of original colony tissue over white plague lesions has never been seen on *M. annularis* colonies.

It is possible that regeneration rates in *M. annularis* are slower than in the past. Also, the lesions associated with white plague are usually larger than those from white pox. White plague and Caribbean yellow band disease which disproportionately affect *M. annularis* and *M. faveolata* are especially virulent diseases (Bruckner and Bruckner 2006). Also, lesions (artificial or natural) surrounded by living tissue, such as those from white pox, may heal faster than those that border on bare or algal covered skeleton such as those from white plague.



Fi

Figure 1. Adjacent colonies of *M. annularis*, with the one on the left apparently healthy and the one on the right entirely dead.

Some colonies of both of these species seem to have more resistance to bleaching and disease than adjacent or nearby colonies (Fig. 1). Future research on different types of zooxanthellae and on the characteristics of different host coral genotypes may shed some light on this interesting phenomenon.

Evidence of recovery in the USVI and elsewhere

Acropora palmata is showing signs of limited recovery in the USVI, including in areas devastated by white band disease about 30 years ago (Gladfelter 1982, Rogers et al. 2003). Few people have followed *A. palmata* populations in precisely the same reef areas over time. Some signs of recovery have been noted at Buck Island Reef National Monument (Mayor et al. 2006), however these observations were before the major 2005 bleaching event that led to at least partial mortality of many colonies there (NPS, unpublished data). Our studies in St. John do not show clear evidence of an increase in number of colonies and in the overall amount of living coral tissue from 2003 through 2007 (Rogers et al. 2008a).

Recent observations indicate presence of new colonies of *A. palmata* in many areas (e.g., Macintyre and Toscano 2007, Zubillaga et al. 2008), but no clear signs of complete recovery back to the numbers (and overall colony condition) from two to three decades ago. One-time observations of the presence of this species are not irrefutable evidence of recovery. Macintyre et al. (2007) found no living *A. palmata* colonies on a bank-barrier reef off Barbados that was formerly dominated by this species.

Conclusions

The 2005 bleaching event and subsequent outbreak of disease caused the biggest decline ever recorded for

USVI coral reefs. No other stressors have caused so much loss, over such a large geographical area, in such a short time. Similar losses were observed in nearby Puerto Rico (Ballantine et al. 2008).

The fate of the coral reefs in the USVI is uncertain, largely because the fate of the major reef-building species, *Acropora palmata* and *Montastraea annularis*, is not known. Global climate change is expected to bring more intense hurricanes, warmer sea temperatures, more bleaching episodes, and ocean acidification, all of which are great concerns. How will these two species deal with these and other stressors in the future? Which of the stressors are amenable to local management and which must be managed on a global basis? What is the human component of global climate change? Extensive bleaching has not been seen on USVI reefs since 2005, but active white plague disease was seen in August 2008 at one of the St. John long-term study sites.

We are certainly not able to predict the future of the USVI seascape. We need to understand the links between human activities and diseases. Although *A. palmata* seems to have a better chance of recovery than *M. annularis*, based on its higher growth rate, greater potential for dispersal via fragmentation, and its greater resistance to bleaching and disease, there is no evidence of significant increases in the number and size of *A. palmata* colonies around the islands in the last five years. We also need to know more about water circulation patterns and connectivity between USVI reefs and upstream sources which have the potential to supply coral and fish larvae to replenish these degraded ecosystems.

Abstract. This study investigates Black Band Disease (BBD) incidence, distribution, and partial mortality effects upon scleractinian corals in the Marine National Monument, Cayos Cochinos (MNMCC). Searches for BBD used 80 m x 40 m plots at three different sites, chosen to represent a putative spectrum of site quality according to scleractinian coral species richness and percentage cover. The benthic community was analyzed using photo-quadrats, and BBD incidence figures were calculated. Colonies displaying BBD were tagged and photographed repeatedly to quantify the progression rate of disease. These same colonies were then re-photographed over the next two years to record colonization and succession data on the revealed skeletons. Incidence of BBD in MNMCC is low, with the impacted site showing only 0.1% of hosts infected. The healthiest site had an even lower incidence of BBD at 0.03%. The intermediate site had the highest incidence of BBD at 0.38%. BBD was found to follow linear and asymptotic patterns of progression rate. The Intermediate site, with the highest incidence was also found to have higher sediment flux than the other sites.

Key words: Black Band Disease, Honduras, Sediment, Coral Ecology.

Introduction

In the global degradation of coral reefs, coral diseases have been identified as one of the most important yet least understood causal factors (Harvell et al. 2004) For example it has been estimated that the disease, White Pox, has been responsible for reducing the population of the Elkhorn coral, *Acropora palmata*, by up to 87% in the Florida Keys during 1996 to 2002 (Sutherland et al. 2004). Black Band Disease (BBD) is unusual in being a microbial consortium upon the surface of a coral, rather than an internal infection (Carlton and Richardson 1995; Cooney et al. 2002; Frias-Lopez et al. 2002; Frias-Lopez et al. 2003). This microbial community is then responsible for creating a chemical environment that digests off and dissolves the coral tissue away from the skeleton (Richardson 1996). Unlike other coral diseases, BBD is often found in low incidences but persists within a reef for long periods, with the black band progressing over the surface of a coral at speeds of 3-10 mm per day (Antonius 1981; Edmunds 1991; Carlton and Richardson 1995). The distinctive patterning of healthy coral, black band and then recently killed white skeleton, makes BBD a distinctive infection on coral reefs. As such it is ideal for visual and ecological surveys, where laboratory analysis and microbiology techniques, such as Carbon Source Utilization Patterns, are not required to identify the pathogen. This facilitates the study of BBD in creating space on a reef for primary spatial competitors to corals, such as macroalgae and sponges. Sedimentation and elevated nutrients have been attributed as causal factors for increased disease prevalence on coral reefs (Bruckner et al. 1997; Kuta and Richardson 2002; Bruno et al. 2003; Nugues and Roberts 2003)

A study by the World Resources Institute, estimated that Honduran rivers provide 80% of all the sediment and over half of all the nutrients in the Mesoamerican Barrier Reef region (Burke and Sugg 2006). The Honduran Marine Protected Area, Marine National Monument Cayos Cochinos (MNMCC), is an archipelago consisting of two rocky islands and 13 smaller sandy cays. The archipelago is situated approximately 10 miles (16 km) off the coast of mainland Honduras and has been shown to be within reach of local river sediment plumes following the severe impacts of Hurricane Mitch in 1998 (Andrefouet et al. 2002). As such this area provides a unique opportunity to study BBD on reefs influenced by sedimentation and disturbance from local rivers (Paris and Cherubin 2008).

This investigation aimed to record BBD incidence at sites representing a spectrum of sediment impact and reef health. BBD progression rates and subsequent successional communities upon the corals were also recorded for inter-site comparison.

Material and Methods

Study site

Initially nine sites were surveyed with 100 m point transects to determine percentage cover of all benthic species. Additionally, scleractinian corals were identified to species level to form a gauge of reef health from percent cover and species richness (English et al. 1997; Hodgson 1999; Hill and Wilkinson 2004). Three sites were then selected out of the nine as putative healthy, impacted and intermediate sites (Fig.1.)

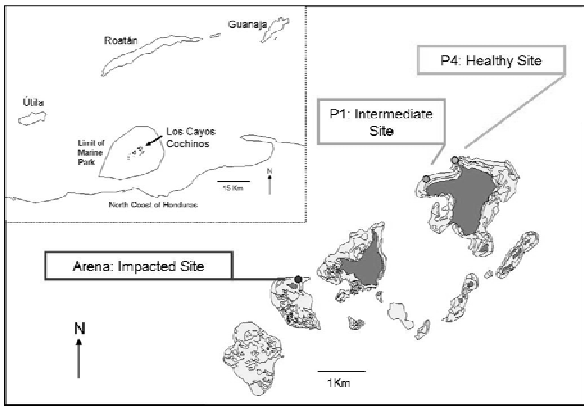

Figure 1: A map or the Marine National Monument Cayos Cochinos (MNMCC) and the three sample sites used in this investigation. Inset is a different scale map, showing the limits of the marine protected area and illustrating the relative close proximity of Los Cayos Cochinos to mainland Honduras. P1 is an abbreviation of Pelican 1 and likewise, P4 is Pelican 4.

At each site a 80 m x 40 m search area was created around permanent transect pins, which in turn had been used as a basis for the initial point transect surveys. The mid point of this 3200 m^2 search area was centered upon the reef crest at each site (6 m depth), thus encompassing both the reef slope and reef flat. 80 m x 40 m was chosen as it was the maximum search area that could be used within one dive, adhering to the local dive safety standards of 50 minutes per dive. Traditional belt transects and radial transects were tried (Kuta and Richardson 1996; Bruckner 2002), but did not cover a large enough area per dive to find incidences of Black band Disease (BDD). The ability to cover 3200 m^2 at each reef, on each dive, allowed daily comparisons of the three sites for new incidences of BDD, whilst monitoring existing infections. Between June and September 2005, colonies affected by Black Band Disease were identified and tagged using 3 mm diameter pins. These colonies were then photographed every day, and using Image Tool 3 software, progression rate and infection surface area were estimated. Colonies were then revisited in 2006 and 2007 for re-photographing and tracking of colony fate, in particular the colonization and succession of reef organisms on the post-BBD exposed skeleton. Other sources of mortality, such as bleaching, predation, burial by sediment or other diseases were also recorded with in the search area. Each 80 m x 40 m plot was then sub-sampled with photo quadrats to estimate the number of potential-host scleractinian colonies that could be infected by BBD according to the species list in Sutherland et al .(2004).

In order to compare site quality and any possible impacts from sedimentation, sediment traps were placed at each site, and suspended sediment sampled from the water column. Sediment traps were built from plastic tubing with a 9:1 optimum length to aperture internal diameter ratio (Bloesch and Burns 1980). This diameter was 7.4 cm and the trap length 67 cm. Baffles were fitted over the mouth to prevent large foreign objects falling into the traps, and to promote sediment capture and retention. Traps were placed on a 6 m isobath, in the center of each 80 m x 40 m plot. Traps were then recovered 7 days later, with the contents passed through pre-weighed Whatman Cellulose Filters (0.45µm) (Butler et al. 2008). Similarly, suspended sediment was determined by collecting one liter of water from near the traps during trap recovery, and then passed over similar pre-weighed filters. Comparison of filtrates allowed the calculation of sediment flux and inter-site comparison of sediment loads.

Results

Of the 14.2% hard coral cover found at the impacted site, Arena, approximately 50% (n=2133) of these corals were estimated to be potential host species for Black Band Disease (BBD). The overall incidence of BBD at this site was found to be 0.1% (n=2). At the healthy site, Pelican 4 (P4), hard coral cover was 15.4%, with around 30% (n=10664) of these corals estimated to be host species for BBD. BBD incidence at this site was the least at 0.03% (n=3). The intermediate site, Pelican 1(P1), had the highest incidence of BBD at 0.38% (n=15), but with lowest hard coral cover at only 5.5%, of which approximately 20% (n=4266) were estimated to be potential host species. The majority of infected corals (n=17 corals) were *Diploria strigosa*, with only 1 infection found upon a *Montastrea cavernosa* and 2 infections being upon *Diploria labyrinthiformis*. Infected corals were all found upon the reef flat at between 7 and 5 m depth.

Revisiting sites found dead portions of coral colonies were dominated by cyanophyta turfs within a month, then within 12 months succeeded by a an approximate 80% covering of *Dictyota* spp. macroalgae. However within 24 months post-BBD

mortality, the *Dictyota* coverage had been reduced, with *Porolithon* spp. covering the majority of the colony as clearly shown in Figure.2. Revision of the plots in 2006 found only 2 new incidences of BBD at Peli 4, 5 at Peli 1 and only 1 new incidence at Arena. In 2007 only 3 new incidences were found at Peli 1 and 1 incidence at Peli 4. No new incidences were found at Arena.

Analysis of BBD band progression rates found that not all infections progress at the same rate (Fig. 3.). Disease bands accelerate across a colony in linear fashions, but also progress in an asymptotic or sigmoid fashion, sometimes slowing down and dissipating altogether to leave patches of colonies alive in partial mortality events.

Sediment flux was found to be highest at Pelican 1, at 11.17 mg/m^2/d, with Arena having the lowest flux at 3.19 mg/m^2/d. Suspended sediment (Suspended Particulate Matter (SPM) was similar at all sites, ranging from 5.35 to 5.42 mg/L.

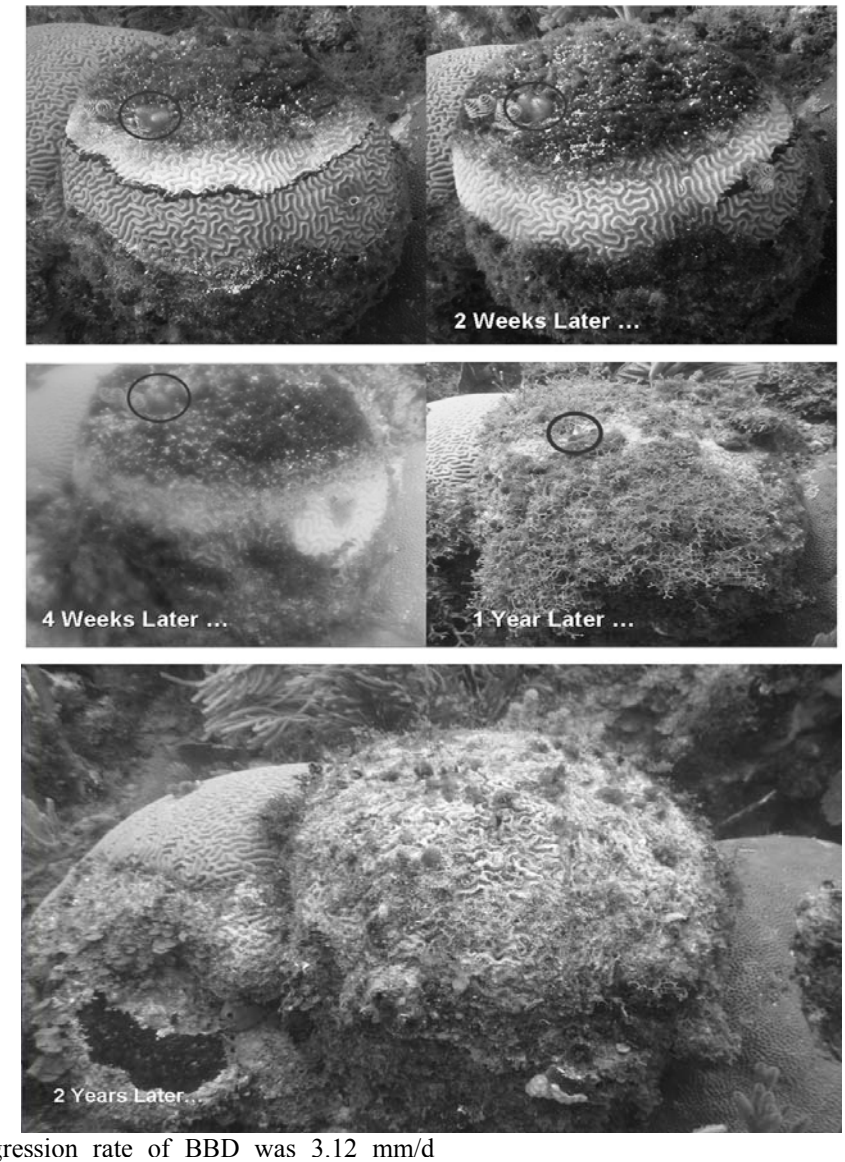

Figure 2: Succession of Black Band Disease and subsequent colonizers on a *Diploria strigosa* colony. Note rapid primary colonization by cyanophyta, then *Dictyota* spp., followed by succession to primarily *Porolithon pachydermum* cover. Circles highlight the same Christmas Tree worm cast as a point of reference

Mean progression rate of BBD was 3.12 mm/d (SE=2.65) at A and 1.45 mm/d

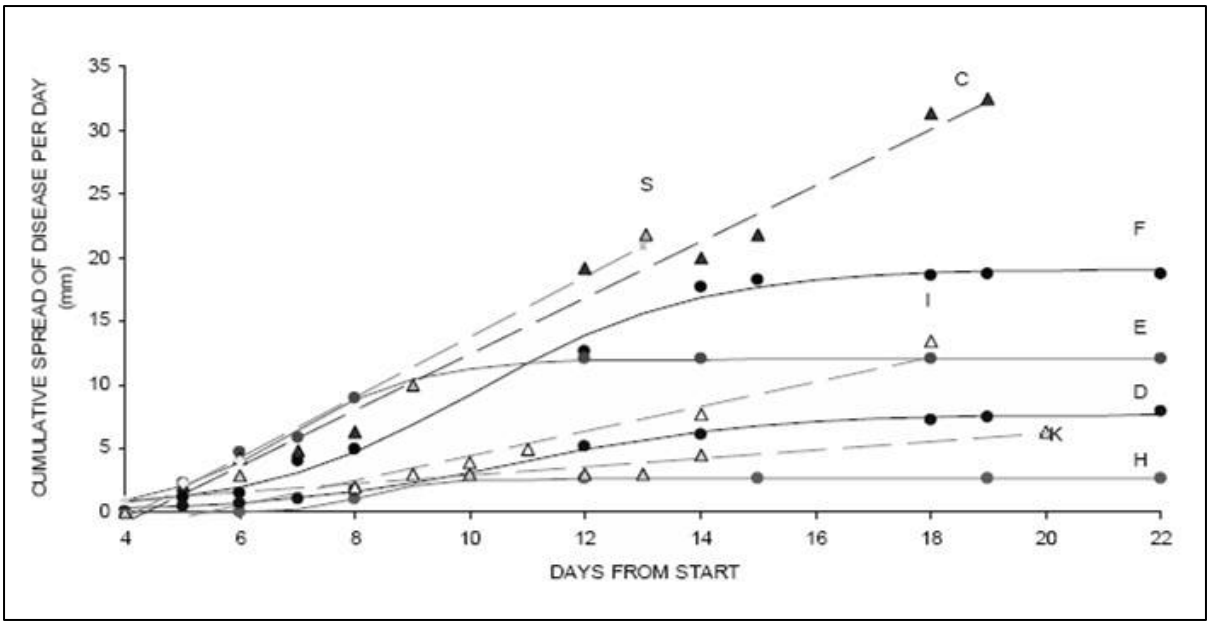

Figure 3: Cumulative spread of Black Band Disease upon 8 *Diploria* spp. colonies with linear response in triangles and dashed lines, and cessation of spread and asymptotic response after 7-14 days in circles and bold lines. Caps identify different colonies.

Discussion

Overall, Black Band Disease (BBD) incidence levels were found to be relatively low at the sample sites in Cayos Cochinos in 2005 (n=20), and continued to decrease in incidence through 2006 (n=8) to 2007 (n=4). This may be due to the period of increased water temperatures in 2005 (Rowlands et al. 2008). Increased temperatures could increase photosynthetic activity in the BBD consortium (Richardson and Kuta 2003) and in turn BBD virulence, or increased temperatures could abnormally stress corals, making them more susceptible to infection. The putative intermediate site in our study, Peli 1, had the highest incidence of BBD (0.38%). A possible explanation is that coral cover and potential host numbers are too low at Arena, the putative impacted site. In contrast the high coral cover and high species richness of the reef community at Peli 4 may be an indication that this putative healthy site is too 'healthy' for high BBD incidence. The sediment traps revealed the putative intermediate site, Peli 1, as having the highest sediment flux (11.17 mg/m^2/d). This higher sediment load than the other sites maybe directly causing BBD, acting as a substrate for cyanophyta mat formation or acting as a source of stress for corals, leaving colonies more susceptible to infection Dissolved nutrients have been found at only trace levels at all sites (Shrives 2007), but a future study could use Nitrogen and Carbon Isotope data or coral cores to better understand the nutrient regime at these sites.

BBD was found to play a part in patch dynamics upon the reef flats of Cayos Cochinos. The progression rate data (Fig.3.) illustrates that not all mortality from BBD resulted in entire colony death, leaving some patches of coral alive. Not all corals suffered from terminal *Dictyota* spp. domination, and often there was a succession to *Porolithon* spp. cover, suggesting that there is either still a reasonably good population of herbivores nearby, or that *Dictyota* spp. are dying back during the winter months. BBD was also observed to be an indirect source of mortality for the Christmas Tree worm, *Spirobranchus giganteus*, often abundant on the *Diploria* spp. colonies photographed and tagged within this study. Post BBD colonies supporting *Spirobranchus giganteus* became obscured by the growth of *Dictyota* spp. and died. In turn, the vacated *S. giganteus* tubes were observed and photographed as a new source of habitat and refuge for Blenniidae.

In conclusion, although found at relatively low incidence levels in Cayos Cochinos, Black Band Disease was found to contribute to the creation of primary space upon these reefs, playing a role in patch dynamics. Incidence levels and progression rates did not correlate as expected with the initial site classification for reef health using hard coral cover and species richness. BBD was also observed to have indirect effects upon the ecology of other fauna around the reef. Although sediment flux was found to

be highest at the study site with highest incidence of BBD, increased site replication and further studies are required to attribute any direct causal factors to disease outbreaks upon the reefs of the Honduran Marine National Monument, Cayos Cochinos.

Acknowledgement
The authors would like to thank Operation Wallacea and the States of Jersey Department for Education, Sport and Culture for funding this project along with the Universities of Oxford and Edinburgh. Special thanks to Dr. G L. Cowie for assistance on sediment trap design and construction and to P. Thompson and J. Riley for assistance in filtering and processing samples. Thanks also to the Honduran Coral Reef Fund for providing permission and logistics to study in Los Cayos Cochinos and a big thank you to the Government and kind people of Honduras for providing support and permission for this study. We would also like to thank Dr. P. A. Henderson and Pisces Conservation for the use of CAP software. Special thanks also to C. Talbott, Caliban and J. Carilli and to all the dive buddies who assisted in the surveys, and whose hard work made this study possible.

Abstract
Yellow band disease (YBD) has had severe impacts on major reef-building corals throughout the Caribbean. Recent data from Bonaire indicates that this disease remains in an epidemic phase showing similar trends compared to the late 1990s. Ten meter belt transects taken at varied depths of *Montastraea* spp. indicate high indices of yellow band lesions. At 5m depth, yellow band rings and lesions were positively identified on an average of 9.4 (87%) colonies per transect while an average of 1.2 (13%) colonies in this depth range appeared healthy. At 10m depth an average of 1.0 (12%) healthy colonies and 8.3 (88%) colonies affected by YBD per 10m transect were counted. At 15m there were an average of 0.7 (17%) healthy colonies and 2.6 (83%) colonies affected by YBD per 10m transect. These studies coincide with recent severe outbreaks in the Indo-Pacific where similar lesions were found on *Diploastrea* spp., *Herpolitha* spp.and *Fungia* spp. Inoculation experiments of Indo-Pacific bacterial isolates under ambient temperatures cause the induction of YB lesions onto *Montastraea* spp. *in vitro*. YBD continues to be in an infectious stage in its original Caribbean hot spots and appears to be spreading in Pacific coral genera.

Key Words: Yellow band, *Montastraea* spp., zooxanthellae, symbiosis

Introduction

The severity of Yellow band/blotch disease (YBD) affecting reef-building Scleractinian corals in the Caribbean (Goreau et al. 1998, Santavy et al. 1999, Cervino et al. 2000, Weil et al. 2006), and Indo-Pacific has been widely documented and has been linked to *Vibrio* pathogens that are genetically related to *V. alginolyticus* and *V. harveii (*Cervino et al. 2004*)*. Yellow band disease targets *Montastraea* spp. throughout the Caribbean and *Fungia* spp., *Herpolitha* spp., and *Diploastraea heliopora* in numerous locations in the Indo-Pacific (Cervino et al. 2008). This is not the first time that *Vibrios* have been implicated in a coral disease; Kushmaro et al. 1996, suggested that vibrionic bacterial bleaching is caused by a temperature-influenced infection by *Vibrio shiloi* (Ben-Haim and Rosenberg 2002). *Vibrio corallilyticus* was also shown to cause bleaching and tissue lysis in the Indo-Pacific coral *Pocillopora damicornis* (Ben-Haim et al. 2003)**.** YBD is having an adverse affect on abundances of these species as rates of infection have reached epidemic proportions.

Research from 1997 to 1998 in Bonaire showed that 91% of *Montastraea* spp. corals at ten research sites were affected by YBD (Cervino et al. 2000). Ten years later, belt transects counted in Bonaire from 2007 to 2008 at the research site Karpata reveal that 86% of *Montastraea* spp. corals are currently affected. Observations of YBD at numerous other sites in Bonaire and Klein Bonaire are consistent with the transect analysis conducted at Karpata.

Yellow band/blotch disease begins as a small lesion (or blotch) about 1-2 cm in diameter. Polyps in the lesion area acquire a somewhat irregular and swollen appearance and pigmentation is lost, giving the affected area a lighter aspect than surrounding healthy tissue. The disease spreads at a rate of about 0.5 cm to 1 cm per month. Gradually, the lesion becomes a yellow ring (or band) of diseased tissue bordered by necrotic tissue often overgrown with algae within and healthy tissue surrounding it. As the diseased tissue advances the ring/band and the dead tissue and algae overgrowth area expands (Fig. 5). The virulence of YBD is greatly enhanced by warmer seawater temperatures (Cervino et

al. 2004) which in the context of global climate change and El Niño events could mean that coral colonies will disappear quicker than they can recover or reproduce (Colwell, R. 1996, Goreau et al. 1998, Harvell et al. 1999, Van Veghel and Bak 1994).

Recent outbreaks of YBD off the fringing reefs of the west coast of Barbados (Brathwaite, pers. comm), together with the list of documented areas where YBD has already been identified (Fig. 1) demonstrate that the disease continues to spread throughout the Caribbean.

Figure 1: YBD has been documented throughout the Caribbean in; Antigua, Bahamas, Barbados, Belize, Bermuda, BVI, Cayman Islands, Colombia, Cuba, Dominican Republic, Florida, Grenada, Jamaica, Mexico, Netherlands Antilles, Panama, Puerto Rico, Roatan, San Salvador, St. Kitts, St. Maarten, St. Vincent and the Grenadines, Turks & Caicos, USVI, Venezuela

Recent field research in Indonesia, the Philippines and Thailand and subsequent laboratory research show that similar lesions on Indo-Pacific coral species are caused by the same pathogens that cause YBD in Caribbean coral species (Cervino et al. 2008). More research is needed in this vast geographical region to determine how widespread vibrio-induced YBD infections currently are, in order to understand the long-term impact on Indo-Pacific coral reefs.

Materials and methods

Prevalence of Yellow band/blotch disease was determined by belt transect counts using SCUBA. Surveys were conducted in August of 2007 and January of 2008. An average of ten transects each (100 linear meters) at depths of five meters, ten meters, and fifteen meters were counted. North and south directions from the site's buoy were covered to avoid overlap of transects done from August 2007 to January 2008.

Bonaire is home to a very large population of *Montastraea* spp. corals and boasts one of the most successful Marine Protected Areas (MPAs) in the Caribbean. Due to these attributes, Bonaire presented a unique opportunity to gauge the status of the region's *Montastraea* spp. health, by studying this area well protected from overfishing, boat anchors, rampant coastal overdevelopment and other stressors that plague the rest of the Caribbean. The study site, Karpata, is a very popular dive site on the northwest coast of Bonaire and has a particularly abundant and densely packed population of *Montastraea* spp. colonies (Bak et al 2005).

Temperatures in August of 2007 ranged from an average of 29° Centigrade at five and ten meters of depth to an average of 28° Centigrade at fifteen meters depth. In January of 2008 temperatures averaged 26° Centigrade at all depths. Only minor bleaching was observed.

An underwater reel with ten meters of measured nylon line was stretched horizontally along the reef and held in place by two divers constantly monitoring depth and tension of the transect line. The survey was conducted along the transect line and all colonies that crossed the line were counted. It should be noted that the underwater topography at 10 and 15 meters depth is a near vertical wall, therefore colonies that fell into the line of sight *behind* the transect line on the wall were counted while at five meters depth the transect line was stretched above the flat reef and all colonies that lie in line of sight *below* the transect line were counted. A series of photos was taken along transects at all depths using an underwater Sony W5 digital camera in August of 2007.

Montastraea spp. colonies with visible signs of YBD were counted as infected. Colonies devoid of visible signs of lesions/blotches or rings/bands and those that showed signs of disease that could not be positively attributed to YBD were counted as healthy. "Healthy" in the context of this paper does not mean that coral colonies were free of other diseases, it means only that Yellow band/blotch disease was not present on that particular colony.

Results and Observations

A survey of the incidence of Yellow band/blotch disease at Karpata was conducted to determine the status of *Montastraea* spp. ten years after the previous survey. Overall, the indices of YBD were very high (86%) in 2007/2008, similar to the findings in 1998 (91%) (Cervino et al. 2000).

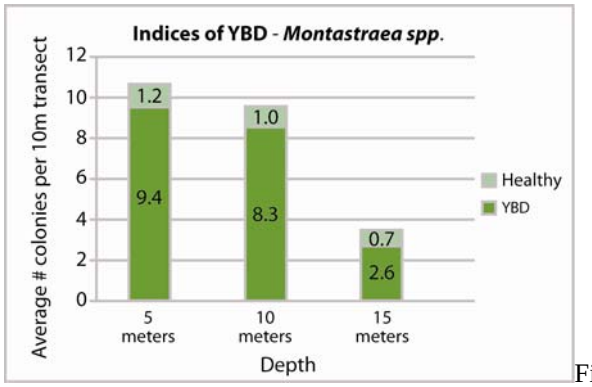

Figure 2: YBD transect results 2007 & 2008 in Bonaire showed high indices of disease as compared with healthy corals.

At five meters depth, an average of 9.4 *Montastraea* spp. colonies per ten-meter belt transect were infected with YBD, as opposed to an average of 1.2 healthy colonies. At the top of the reef, in the five-meter range, many colonies are lobate *Montastraea annularis* or relatively small colonies of *Montastraea faveolata* whose morphology may explain why smaller blotches were the most observed sign of disease at this depth. There remains a relative abundance of live coral cover at this depth though the majority (87%) of colonies show signs of infection.

At ten meters, the sloping wall has a large number of densely packed, mountainous *Montastraea faveolata* colonies. These colonies are often larger than the colonies counted at five meters and the surface area of the *M. faveolata* is by and large more continuous than that of *M. annularis*, which is abundant at shallower depths. An average of 8.3 *Montastraea* spp. colonies per ten-meter belt transect showed signs of YBD while 1.0 colonies appeared to be healthy. Relative abundance of live *Montastraea* spp. colonies is lower at ten meters than at five meters however the incidence of corals infected with YBD was slightly higher at eighty-eight percent (88%).

The reef at fifteen meters is topographically similar to the reef at ten meters. An average 2.6 *Montastraea* spp. colonies per 10-meter belt transect were found to be infected with YBD and an average of 0.7 colonies were exempt from signs of the disease. The number of colonies counted at this depth was noticeably lower since most *Montastraea* spp. colonies at this depth were dead or nearly dead (more than 75% loss of live coral tissue) and were overgrown with algae, sponges, tunicates and recruits of other coral species. Many of these colonies were at such advanced stages of tissue loss that it was difficult to diagnose the cause of death. Overall, eighty-three percent (83%) of *Montastraea* spp. colonies that remain at this depth were infected with YBD.

Similarly, at six field sites in the Wakatobi Island chain, Indonesia 15 m x 1 m belt transect counts were conducted which found 34 (19%) *D. heliopora* colonies infected with YBD and 531 (42%) *Fungia* spp. colonies infected with YBD. These numbers reflect the dominance of *Fungia* spp. at the Wakatobi reefs and show an analogous trend to the outbreak of YBD on the primary reef-building *Montastraea* spp. colonies in Bonaire. It would appear, then, that an abundance of a particular susceptible species yields high indices of YBD infection and its spread may be density dependent.

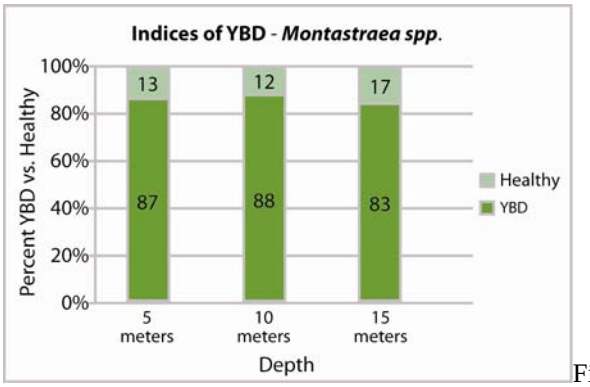

Figure 3: Percentage of YBD infected *Montastraea* spp. colonies in Bonaire - transect results 2007 & 2008

Discussion

According to recent reports from scientists and divers, *Vibrio* induced Yellow band lesions throughout the Caribbean have not diminished. Nor have YBD infected colonies in Bonaire recovered since they were reported in1997. *In situ* studies and recent new outbreaks indicate that this epidemic has lasted over a decade in the Caribbean and Florida.

YBD is caused by a consortium of four novel *Vibrio* spp. together with *Vibrio alginolyticus*, a well-known shellfish pathogen (Cervino *et. al*. 2008). YBD is a disease of the symbiotic algae and not of the host coral as the microbial consortium attacks the zooxanthellae *in situ* within the gastroderm causing lysing of zooxanthellae (Cervino et al. 2004). Vacuolization and fragmentation occur and severe impairment of the thylakoid membranes cause loss of chlorophylls a and c_2, which impairs photosynthetic functionality. (Cervino et al., in prep).

Were it not for the important benefits of association with their symbiotic algae, coral hosts would be unable to lay down calcium carbonate skeleton at the same rate as they have done for centuries. Benefits of photosynthesis and fixation of carbon provided by the zooxanthellae are necessary for the growth of the coral host (Muscatine and Cernichiari 1969, T.F. Goreau et al. 1979, Muller-Parker and D'Elia 1997). Corals that are infected with YBD and other diseases experience slower

growth rates, and due to a great net loss of biomass, coral colonies experience a reduction in ability to reproduce (Antonius, A. 1977 1981, Peters 1984, Kojis and Quinn 1985, Szmant 1991, Goreau et al. 1998, Porter et al. 2001).

The exact mechanism by which the *Vibrio* consortium actually causes disease is still unknown. However, we hypothesize that the mode of adhesion is similar to what Banin et al. *(2001)* showed when *Vibrio shiloi* biosynthesized and secreted an extracellular peptide - toxin P - that impaired and inhibited photosynthesis of symbiotic zooxanthellae. The first physical barrier to infection for most corals is the mucopolysaccharide layer, which in healthy coral colonies is home to a plethora of coral-associated microbes that play an important role in antibacterial activity (Hayes and Goreau 1998). Pathogenic stress, or environmental stress, such as a thermal bleaching event, can alter the microbial community commonly associated with a particular species (Frias-Lopez et al. 2002, Bourne et al. 2007). It is possible that opportunistic microbes – in this case, the YBD *Vibrio* consortium - repopulate the mucus layer after such events, causing disease (Knowlton and Rohwer 2003, Ritchie, K.B. 2006, Gil-Agudelo, D.L. et al. 2007, Rosenberg et al. 2007).

These factors have great implications for the health and abundance of the major Caribbean reef-building *Montastraea* spp. colonies whose numbers are in decline throughout the region.

Yellow band/blotch disease in the Indo-Pacific

YBD is currently also affecting reef-building corals in the Indo-Pacific. Field studies and laboratory experiments by Cervino et al. have shown that similar pathogens are causing similar symptoms of disease in *Fungia* spp., *Diploastraea heliopora*, and *Herpolitha* spp. colonies.

Inoculation experiments, conducted at the Mote Marine Laboratory in Summerland Key, Florida in 2007, of *Montastraea faveolata* fragments with the *Vibrio* spp. isolated from diseased Indo-Pacific corals in aquaria resulted in YBD infection (Fig. 4). Interestingly, inoculation of the *M. faveolata* fragments from the 26° and 28° C tanks resulted in infection while identically inoculated fragments in the 30° and 32° C tanks did not result in infection.

Figure 4 – M. faveolata fragments from 26° C tank, inoculated with Indo-Pacific consortium, resulted in YBD lesions.

It is important to note that Yellow band disease infections were not found to be more prevalent with warmer seawater temperature. However, when YBD-infected corals from ambient temperature tanks were moved to warmer temperatures the disease became more virulent. In other words, corals are apparently susceptible to YBD infection when seawater temperatures are normal, and the disease is more likely to spread during warmer periods.

Conclusion

There is still much to understand regarding the mechanism of host-alga transmission that leads to infection in YBD. That need is more compelling than ever in light of the recent Indo-Pacific outbreaks and the connection between infectivity at normal seawater temperatures and virulence with rising seawater temperatures. As Cervino et al. 2004 2008, have shown, YBD is no longer only a disease of Caribbean coral species, but it is now having a large impact on the reef-building corals of the Indo-Pacific. Further investigation should include laboratory analysis of the zooxanthellar clade subtypes that are affected and YBD's possible connection to aquaculture pathogens. The negative implications of a widespread infectious disease such as YBD are numerous. Besides disease, corals must deal with myriad debilitating stressors – both anthropogenic and non - such as predation, bleaching events, pollution, sedimentation and overfishing. The environment is

quickly changing; the sum of all these ills and the accelerated timescale might be more than corals can adapt to. A strong working knowledge of the problem is essential for effective coral reef management and efforts to mitigate the damage to coral reefs around the world.

Abstract. The surface mucopolysaccharide layer (SML) is an energy rich environment that supports host-specific microbial communities. Studies have shown that the coral surface microbiota shift, in both richness and abundance, correlated with environmental perturbations and pathogens. Thus, surface microbiota may play a mutualistic role in the health of the coral host, analogous to the role of human gut microbiota. Indeed, we hypothesize that the coral surface microbiota play an integral role in disease resistance and that perturbation of the microbiota increases disease susceptibility. Here, we report on *in situ* experiments to test whether the structure of the surface microbiota of the Caribbean sea fan, *Gorgonia ventalina,* responds to perturbations in the local environment. Specifically, we tested the effects of light reduction, nutrient enrichment, antibiotic wash, and pathogen (*Aspergillus sydowii*) exposure on the microbiota as characterized using DGGE. Results indicate that the structure of the surface microbiota changes in response to perturbation and that some bacterial strains were present in untreated control corals and remained throughout all treatments. This provides experimental evidence that the surface microbiota are a link between the coral, their environment, and potentially their health. Yet the response to the perturbations appears to be complex, and most likely are the result of primary and secondary interactions between the environment, microbiota, mucus, and coral host.

Key words: Surface mucopolysaccharide layer, Microbiota, Pathogen, Perturbation, DGGE

Introduction

The correlation of incidence of coral disease with elevated seawater temperatures (Hoegh-Guldberg 2004), increased pollutants (Kim and Harvell 2002; Kaczmarsky et al. 2005), nutrient enhancement (Bruno et al. 2003), and light intensity (Richardson and Kuta 2003) suggest that environmental conditions play a role in pathogenesis. At present, the mechanisms connecting environmental factors and disease are not well understood. However, recent studies have pointed to microbial associates of corals as a possible link between environment and disease (Kaczmarsky 2006; Reshef et al. 2006).

Coral microbial associates reside primarily within or upon a surface mucopolysaccharide layer (SML) secreted by the coral host (Rohwer et al. 2002) to protect against UV light, desiccation, and to cleanse them of sediments. The SML consists of polysaccharides, proteins, lipids, and fatty acids (Meikle et al. 1988) and represents an important nutrient source in reef ecosystems (Wild et al. 2004). Microorganisms, take advantage of this with the SML supporting species-specific (Rohwer et al. 2002) and abundant microbial communities (Ritchie, Smith 1995; Brown and Bythell 2005).

However, given the paucity of information about the role of SML microbial communities of corals, hereafter referred to as surface microbiota, the vertebrate system provides a useful model for gaining insights and developing testable hypotheses. For instance, vertebrate surface microbiota act as an obstacle to pathogen colonization (Fredricks 2001; Bojar and Holland 2002). Perturbation of the microbiota from antibiotics, for example, may facilitate proliferation of less abundant and potentially pathogenic strains of bacteria, or allow non-resident microbes to colonize (Lysenko et al. 2005). This function of resistance by the microbial community is called 'colonization resistance' and is an important part of disease resistance (van der Waaij 1989).

In corals, like vertebrates, some of the surface microbes may confer disease resistance. Indeed, Reshef et al. (2006) suggest that the microbiota of corals are 'probiotic' in that the surface microbiota adapt and facilitate resistance against pathogens. Here, we hypothesize that the surface microbial communities change in response to exposure to a pathogen and environmental perturbation. If the SML microbial communities do change, then this provides evidence that surface microbiota may help mediate coral health. Shifts would indicate a stressed system

and could represent increased disease susceptibility. Consistent with this hypothesis, several studies have reported that surface microbiota of diseased corals are different from healthy ones when compared quantitatively and qualitatively but have not included environmental effects. For example, different surface microbial communities were documented on diseased areas of *Montastraea annularis* corals than on healthy (Frias-Lopez et al. 2002; Pantos and Bythell 2006), and a more diverse microbial community has been detected in diseased relative to healthy corals (Bythell et al. 2002; Pantos et al. 2003). Changes to the microbiota of corals were also found during times of environmental stress, such as during thermal bleaching events (McGrath and Smith 1999). Also, differences in the microbiota were detected on corals depending on coastal proximity and depth (Klaus et al. 2005) as well as across seasons (Guppy and Bythell 2006).

While these correlative studies suggest that the microbiota respond to environmental change, to date, no direct experimental evidence has been provided. The goal of this research is two-fold: first to document experimental perturbation of the coral surface microbiota, and second, to provide support to what we refer to as the "Coral Microbiota Disease Hypothesis." This hypothesis posits that the surface microbiota play an integral role in mediating disease susceptibility and that any perturbations to the structure of the microbiota increase disease susceptibility. Using the *Gorgonia-Aspergillus* pathosystem, coral fragments were subjected to treatments of antibiotics, light disruption, and nutrient enhancement *in situ* to document changes in coral surface microbiota.

Material and Methods

Study site. All of the field collections and experiments were carried out at Pickles Reef (24°59.079' N, 80°24.978' W), located 14.5 km off Key Largo in the Upper Florida Keys during August 2006.

Experimental Design: Three fragments (~16 cm^2) were cut from the edge of *Gorgonia ventalina* sea fans and haphazardly assigned to a treatment, a control, and initial sample. The initial sample was sealed in a sterile plastic bag and transported to the lab in a cooler filled with seawater from the collection site for processing. The two additional fragments were fastened onto a PVC rack that was anchored to the reef substrate for 10 days. Using this design with the coral fragments (same genotype exposed to different treatments), the following three experiments were carried out.

Antibiotic Treatment. The coral fragments from two apparently healthy colonies were treated with an antimicrobial wash (50 μgml^{-1} gentamycin, 100 μgml^{-1} rifampicin, and 100 μgml^{-1} streptomycin in sterile seawater as per Buyer et al. (2001)). Half of the fragments were inoculated via attachment of a pathogen strip consisting of a sterile piece of gauze (1 x 2 cm) embedded in a thin layer of agar overgrown with the fungal pathogen *Aspergillus sydowii*.

Light Disruption. Apparently healthy coral fragments from three colonies were anchored to PVC frames on the reef substrate and were covered by shade cloth laid over a clear sheet of plexiglass (to provide structural support for the shade cloth). As a control, fragments were put under the plexiglass only.

Nutrient enhancement. Increased nutrients were administered to coral fragments taken from three apparently healthy or three actively diseased parent colonies and fastened to the PVC frames. This was done by placing time-release fertilizer (Osmocote Flower and Vegetable Plant Food, N-P-K: 14-14-14, Marysville) in "nutrient pillows" per Bruno et al (2003) that were secured next to each anchored fragment. Control pillows were filled with rinsed pebbles.

Mucus Collection and DNA Extraction: All coral fragments were collected after 10 days and transported to the lab. Mucus was collected from each fragment by vortexing for 1 min in 40 ml of sterile seawater. After vortexing, the coral fragment was removed and the remaining slurry was stored at -80°C for three months until molecular analysis. Mucus and seawater samples were thawed and centrifuged three times (5 min at 10,000x g) and the DNA in the mucus concentrate was extracted using protocol outlined in the Power Soil DNA Isolation kit (Mo Bio, California) and eluted to a final volume of 1000 µl. DNA concentration was determined using a spectrophotometer set at 260 nm.

PCR Amplification: A nested PCR procedure was used to amplify bacterial 16S rDNA using primer sets previously described to analyze coral bacteria (Pantos et al. 2003). The first round of PCR used primers pA (8F) and pH'(1542R) with a minimum DNA concentration of 10 ng/µl. A touch-down PCR cycle was used following protocol from (Cooney et al. 2002). Products were verified by agarose gel electrophoresis and 5µl used as template for the second round of amplification using the primers Pc (341F) with a GC rich clamp incorporated to the 5' end, and pE'(928R). The nested products were purified and concentrated to 30 µl using a QIAquick purification kit (Qiagen, Valencia).

DGGE Analysis: Denaturant gradient gel electrophoresis was conducted using The D-Code universal mutation detection system (Bio-Rad, California). The nested and purified products were resolved on 6% (w/v) bis-acrylamide gels across a 25 to 50% denaturant gradient to select for fragment

number and sizes appropriate for analysis. 10uL of each nested product was loaded into each lane and run for 12 h at 90 V at 60° C. Gels were stained with Sybr Gold (Sigma, California) for 20 min and visualized with a UV transilluminator. Gel images were captured using Quantity One D-Code imaging software (Bio-Rad, California).

Statistical and OTU analysis: Bacterial operational taxonomic units (OTUs) seen as bands were defined by band-matching analysis as part of the Quantity One D-Code imaging software (Bio-Rad, California). The inclusion of uncertain bands was based on sensitivity of > 1%, such that a band was recognized relative to background pixels color intensity. A 1kb mass ladder (Fisher Scientific, Pennsylvania), manually defined in the software was used in a marker lane for between-gel comparisons. Mean OTUs and treatment effects were analyzed across all gels by 1-way ANOVA and 2-tailed T-tests (JMP). Multivariate cluster analysis (Mean Hierarchical algorithm, JMP, Version 5) were done by comparing samples to composites of OTUs using presence/absence of bands, to determine similarity in DGGE profiles.

Results

Out of all the samples there was a maximum of 22 OTUs, with presence or absence of at least 1 to 8 unique OTUs that correlated with coral treatment. Arrows labeled 5 and 6 indicate unique bands present in some samples but absent in others from the DGGE gel. There were also OTUs common across all treatments, including seawater and first round amplification control samples at arrows 1-4, and 10 (Fig.1). The presence of bands in the seawater, filtered water, and first round amplification (C1) indicate microbes similar to all SML samples and seawater amplified during the first round of nesting. Yet absence of bands in lane labeled C2 indicates that there was no contamination after two rounds of amplification.

The mean richness, determined as total OTUs per mucus sample, across all treatments in all gels was 11 (SE=2.66). The minimum OTU richness was 4 with maximum of 22 and the mode was 8. Overall, OTU richness showed no significant difference among samples of the same environmental perturbation treatments (1-way ANOVA, Antibiotic: F=0.05, P=0.99; Light: F= 0.148, P=0.87; Nutrient: F= 0.60, P=0.56; 2nd & 3rd gels not shown; Figs. 2A, 3A, 4A).

The DGGE data were analyzed using a cluster analysis based on OTU presence/absence to reveal similarities among communities of SML microbiota (Figs. 2B, 3B, 4B & 5).

Antibiotic Treatments. Cluster analysis revealed OTU profiles from the initial healthy sample and the combination treatment of pathogen and antibiotic together, were more similar to each other than to the control (Fig.2B).

Light Disruption. Cluster analysis revealed profiles of the healthy and shaded samples were more similar to each other than to the control (Fig.3B). The initial samples from like colonies were more similar to the control than the shaded.

Nutrient Enhancement. Cluster analysis indicated OTU mucus profiles from initial disease, pathogen only, and the nutrient enhancement, shared 8 OTUs from a composite total of 20. Together these profiles were more similar to the control, than the initial healthy. The sample that was both diseased and nutrient enhanced was more similar to the initially healthy than the initially diseased. The two most dissimilar profiles were the initially healthy and initially diseased, with difference of 10 OTUs, yet both when subjected to increase in nutrients became more similar (Fig.4B).

All treatments. Overall, cluster analysis revealed OTU profiles were more similar based on original sea fan colony than on treatment, although more similar profiles were obtained from like treatments than not (Fig.5).

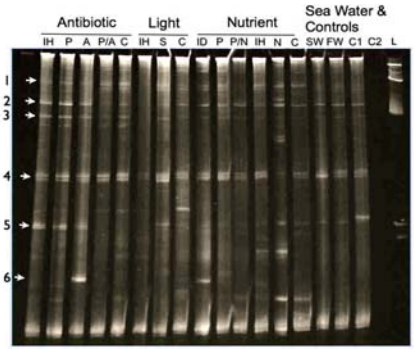

Figure 1: DGGE image depicting 16S rDNA profiles. Bands of operational taxonomic units (OTUs) represent possible unique strains of bacteria. Numbered arrows indicate OTU sites unique to some treatments (5 & 6), and those found across all treatments (1-4). Lanes are labeled by treatment given to coral fragments: IH=initial healthy, P=pathogen, A=antibiotic, C=control, S=shaded, ID=initial diseased, N=nutrients, FW= filtered water.

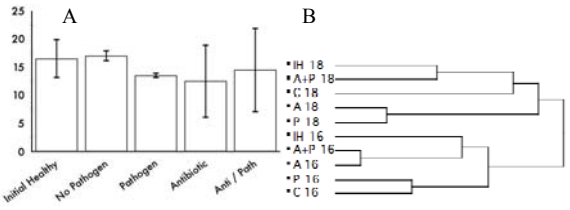

Figure 2: Mean OTU Richness (A) and Similarity of Molecular Profiles (B) from Antibiotic Treatments. Richness (± SE) is from all gels. Clusters are labeled by treatment given to coral fragments: IH=initial healthy, P=pathogen, A=antibiotic, C=control, S=shaded, ID=initial diseased, N=nutrients. Numbers indicate the original fragment colony.

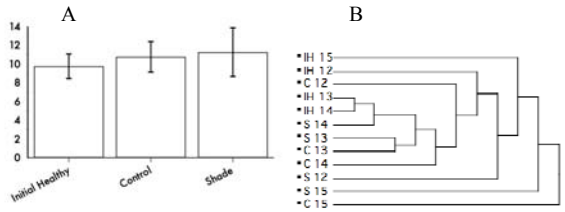

Figure 3: Mean OTU Richness (A) and Similarity of Molecular Profiles (B) from Light Disruption Treatments. Richness (± SE) is from all gels. Clusters labeled by treatment given to coral fragments: IH=initial healthy, P=pathogen, A=antibiotic, C=control, S=shaded, ID=initial diseased, N=nutrients. Numbers indicate the original fragment colony.

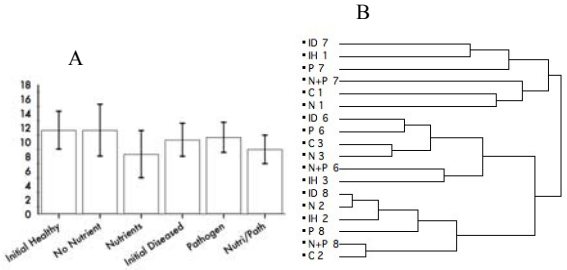

Figure 4: Mean Bacterial Richness (A) and Similarity of Molecular Profiles (B) from Nutrient Enhancement Treatments. Richness (± SE) is from all gels. Clusters labeled by treatment given to coral fragments: IH=initial healthy, P=pathogen, A=antibiotic, C=control, S=shaded, ID=initial diseased, N=nutrients. Numbers indicate the original fragment colony.

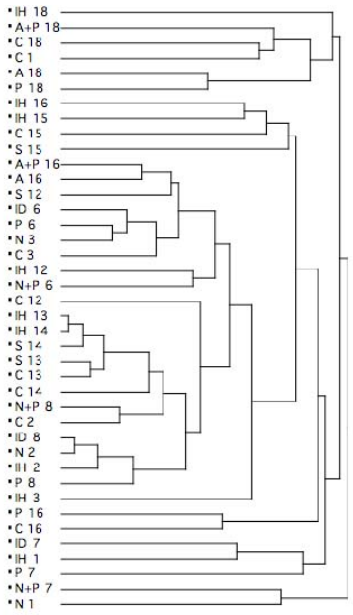

Figure 5: Similarity of Molecular Profiles across all treatments. Clusters labeled by treatment given to coral fragments: IH=initial healthy, P=pathogen, A=antibiotic, C=control, S=shaded, ID=initial diseased, N=nutrients. Numbers indicate the original fragment colony.

Discussion

Variations in molecular profiles of the coral SML microbiota were detected when sea fan fragments were infected by a pathogen, treated with antibiotics, subjected to reduced light levels, and exposed to elevated nutrient levels *in situ*. Some OTUs, potential bacterial strains, were present in control corals and remained throughout all treatments. This finding is consistent with the Coral Microbiota Disease hypothesis that posits that surface microbiota play an integral role in mediating disease susceptibility.

The shifts in the microbes demonstrated by this study may not have been statistically significant because of the DGGE gradient used. It is possible that more OTUs could have been detected because there appeared to be high concentrations of DNA the top and bottom of the gel (Fig. 1). Another consideration is that PCR bias may have caused preferential amplification of sequences that resulted in more similar OTU profiles. PCR artifacts have been shown to effect results of 16S rDNA diversity analysis (Acinas et al. 2005).

The microbes may in fact be responding to a change in mucus quantity or quality and not directly to the treatments. The microbial communities living in the SML are thought to rely on exudates from the coral-zooxanthellae association (Ducklow and Mitchell 1979; Gil-Agudelo et al. 2006). It would follow that alterations in the microbial community would occur if the coral-zooxanthellae relationship were altered. A change in nutrient and or light availability may alter the coral-zooxanthellae symbiosis and in turn affect the nature of the SML qualitatively (i.e., composition) or quantitatively. For instance, studies have also shown that copious mucus production is often the first visible sign of a generalized response by corals to environmental stress (Peters 1984).

Not to be disregarded are the potential roles of innate host response and microbial interference. Kim et al. (2000) demonstrated that the sea fan *G. ventalina* is capable of a chemically mediated inducible response against the pathogen *A. sydowii.* It may take considerable amounts of energy for the corals to produce these defensive compounds, which come at the expense of secreting the protective mucus layer (Edmunds and Davies 1989). It would follow then, that alterations in the microbial communities, which utilize the SML, would result. Alternately, diseased corals may reduce the production of these compounds so that they can maintain "normal" mucus production.

It was suggested that *G. ventalina* may respond to *A. sydowii* with a non-specific antimicrobial product regardless of whether it is fungal or bacterial (Alker et

al. 2004). The inhibitory compounds could affect non-targeted microbes. Also, some SML microbiota themselves produce antimicrobial compounds (Castillo et al. 2001; Ritchie 2006).

In the present study, host factors did appear more important to microbial diversity than direct perturbation. Particularly in the cluster analysis from all treatments that show the sea fan of origin was a better predictor of microbial similarity than the pathogen or perturbation it was exposed to. Yet, due to a lack of knowledge about microbial interactions, innate host response, SML antimicrobial products, and environmental effects, it is hard to know if the microbial shifts noted herein were affected by any or all of these factors.

Abstract. Several microorganisms have been identified as pathogenic agents responsible for various outbreaks of coral disease. Little has been learned about the exclusivity of a pathogen to given disease signs. Most pathogens have only been implicated within a subset of corals, leaving gaps in our knowledge of the host range and geographic extent of a given pathogen. PCR-based assays provide a rapid and inexpensive route for detection of pathogens. Pathogen-specific 16S rDNA primer sets were designed to target four identified coral pathogens: *Aurantimonas coralicida, Serratia marcescens, Vibrio shilonii,* and *Vibrio coralliilyticus*. Assays detected the presence of targets at concentrations of less than one cell per microliter. The assay was applied to 142 coral samples from the Florida Keys, Puerto Rico, and U.S. Virgin Islands as an *in situ* specificity test. Assays displayed a high-level of specificity, seemingly limited only by the resolution of the 16S rDNA.

Key words: coral disease, pathogen, bacteria, detection assay, PCR.

Introduction

The study of coral microbiology has been largely fueled by investigations of disease. These studies have been aimed at identification of specific pathogenic agents, followed by the classical method for confirmation of disease causation by fulfillment of Koch's Postulates (Koch 1882). In this manner, numerous putative pathogenic agents have been identified (reviewed in Rosenberg et al. 2007).

Due to the opportunistic manner in which disease samples must often be collected, many coral pathogens were identified based upon limited host, geographic, and temporal occurrences of disease. The tendency to group occurrences of coral mortality with similar gross lesion morphologies into named diseases, has often led to the assumption that all instances of a given "disease" are identical. By extension, the practice has propagated the idea that a given pathogen is responsible for all pathologies with similar lesions. Recent evidence, such as the observation of apparent white plague disease in the absence of the published pathogen (Pantos et al. 2003), has brought these assumptions under scrutiny.

The use of PCR has become very commonplace, with most research facilities having access to the required equipment and expertise. Pathogen-specific PCR assays have been extensively utilized for the detection of various human and veterinary pathogens; evolving into a relatively simple and inexpensive detection method. These assays have the advantage of selectively identifying target sequences from a population and provide a route for further confirmation through sequencing of the amplicons.

This study details construction and testing of PCR primers specifically targeting four bacteria previously implicated in coral disease, *Aurantimonas coralicida*: white plague (type II) (Richardson et al. 1998), *Serratia marcescens*: white pox (Patterson et al. 2002), *Vibrio shilonii*: bleaching (Kushmaro et al. 1997), and *Vibrio coralliilyticus*: bleaching and necrosis (Ben-Haim and Rosenberg 2002). Also presented is the application of these primer sets to healthy and diseased corals in the Florida Keys, Puerto Rico, and U.S. Virgin Islands. These assays represent cost-effective mechanisms for rapid, initial screening for the presence of the target microbes.

Materials and Methods

Bacterial Strains

Aurantimonas coralicida WP1 (DSMZ 14790) (Denner et al. 2003), *Serratia marcescens* PDL100 (ATCC BAA-632) (Patterson et al. 2002), *Vibrio shilonii* AK-1 (ATCC BAA-91) (Kushmaro et al. 2001), and *Vibrio coralliilyticus* YB (ATCC BAA-450) (Ben-Haim et al. 2003) were used as target bacteria for primer design, sensitivity, and specificity testing. *Escherichia coli* (ATCC 8739) and strains of *Vibrio* spp., *Photobacterium* spp., and *Shewanella* spp. bacteria isolated from healthy acroporid corals (Polson 2007) were used as additional control strains during specificity testing.

Extraction of DNA

Bacterial cultures were grown on glycerol artificial

sea water (GASW) agar media (Smith and Hayasaka 1982) for 18 hr (except *A. coralicida*, 36 hr). Single colonies were transferred to a PCR tube containing 150 µl of QuickExtract reagent (Epicentre). Each was incubated at 65ºC for 30 min and 98ºC for 16 min with vortexing at each step.

DNA extractions from environmental samples were performed by processing 200 µl of liquid sample (mucus, seawater, or mucus-tissue slurry) or ~0.5-1g of cryo-milled coral fragments using the FAST DNA Spin Kit for Soil (Qbiogene) according to modifications of Webster *et al.* (2003).

Primer Design and PCR Optimization

Sequence data for the 16S rDNA of a given target bacterium, sequences from closely related bacteria, and outlier sequences were aligned using Lasergene MegAlign (DNAStar). Primer sequences were chosen from regions with increased variability between target and comparison sequences. Each primer sequence was checked for specificity by BLAST against GenBank nucleotide database and analysis with the Ribosomal Database Project's (RDP) Probe Match. Candidate primers were checked for interfering secondary structure with Lasergene PrimerSelect (DNAStar).

Temperature gradient PCR was run on each candidate primer pair using DNA from the target bacterium as template. Approximately 10 ng of DNA template (optical density 260 nm) was added to PCR mixture (2mM $MgCl_2$, 0.2 mM dNTP (each), 0.2 µM primers (each), 1.25 U ExTaq Polymerase (Takara)) with the following thermal cycle: 95ºC-5min; 30 cycles: 95ºC-30s, 62ºC±10ºC-30s, 72ºC-60s; 72ºC-10min. PCR products were visualized by electrophoresis on a 1% agarose gels post-stained with ethidium bromide. Annealing temperatures were chosen based on highest annealing temperature producing a consistently visible PCR product.

Selected primer sets (Table 1) were compatible with a uniform annealing temperature of 67ºC. Final conditions for assay: 10-20 ng of DNA were added to 50 µl reactions using the standard mixture and PCR was performed: 95ºC-5min; 30 cycles: 95ºC-30s, 67ºC-30s, 72ºC-60s; 72ºC-10min. Amplicons were visualized by gel electrophoresis (Fig. 1).

Primer Specificity

One hundred forty-two samples of coral mucus/tissue or seawater, collected from reefs in the U.S. Virgin Islands National Park (USVINP), St. John, U.S. Virgin Islands, Florida Keys, and southwestern Puerto Rico, were used as material for testing primer specificity. DNA extraction, PCR, and amplicon visualization were performed as described earlier. Suitable PCR bands were excised from agarose gels.

Gel purification was performed using the NucleoSpin Extraction Kit (Clontech). Amplicons were cloned by use of the TOPO TA Cloning Kit (Invitrogen). Plasmids were purified using the QIAprep 96 Turbo kit (QIAGEN) and sequenced with standard M13F and M13R primers.

Assay Sensitivity

GASW broth was inoculated with 1ml of an overnight broth culture of a target microbe or *E. coli*. Flask cultures were incubated at 25ºC with shaking until mid-logarithmic growth phase. Two 25ml volumes were centrifuged at 4ºC for 10 min at 3500 X *g*, washed in filter-sterilized artificial seawater (FASW; 35 ppt), resuspended in 25 ml of FASW, and frozen at -80ºC (mimicking sample collection protocol). Three 1 ml sub-samples of the growth culture were serially (10-fold) diluted in FASW and 100 µl of the 10^3 through 10^6 fold dilutions were spread onto GASW agar, incubated at 25ºC until sufficient colony growth and colony forming units (cfu) determined.

The 25ml volumes were thawed and diluted to 10^6 cfu per ml. Each was then diluted with washed *E. coli* cells (10^6 cfu/ml), reducing concentration of target microbes, but maintaining a background of 10^6 cfu/ml. Fifteen standards were prepared ranging from 1000 to 0.31 cells/µl (extrapolated from cfu/ml data). DNA was extracted from each sample as described for environmental samples and PCR amplifications were conducted as described for assay PCR.

Results

Primer Specificity

The 142 samples (mucus, slurry, milled, and water) screened for the presence of the four target microbes

Table 2. Environmental sample results used in primer specificity testing. Numbers denote positive results by PCR assay for each target microbe.

	Florida Keys	Virgin Islands	Puerto Rico	**Total**
# of Samples	**67**	**24**	**51**	**142**
A. coralicida	4	5	4	**22**
S. marcescens	0	7	13	**11**
V. shilonii	5	0	1	**6**
V. coralliilyticus	4	0	3	**7**

resulted in 46 positive amplifications (Table 2). All amplicons produced from *A. coralicida* primer sets resulted in clone sequences consistent with the target organism. In all cases the highest sequence homology to a characterized strain was to *A. coralicida*.

Amplicons indicating positive matches for *S. marcescens* resulted in closest homology to *S. marcescens* strains by BLAST and RDP Seqmatch. Some sequences, while 100% identical to *S. marcescens* strains, were also indistinguishable from bacteria identified in the BLAST database as *Kluyvera ascorbata*.

Vibrio shilonii amplicons displayed very close homology to *V. shilonii* strains, but it should be noted that strains of *V. mediterranei, V. aestaurianus, V. ichthyaenteri,* and *Listonella anguillarum* (=*V. anguillarum*) often show very high homology to the known *V. shilonii* sequences. Similarly, *V. coralliilyticus* primers resulted in sequences consistently displaying high identity with *V. coralliilyticus*, but often also similar to *V. neptunis, V. brasiliensis,* and *V. shilonii.*

Assay Sensitivity

Amplification of target DNA was, in all cases, possible at concentrations below 1 target cell/µl. *S. marcescens* and *V. coralliilyticus* primers sets produced easily visible bands at the minimum tested concentrations of 0.31 target cells/µl. The *A. coralicida* primer set produced easily visible bands to 5 cells/µl, with detectible product to 0.31 cells/µl. The *V. shilonii* primer set produced properly-sized amplicons (~600 bp) to 0.62 cells/µl. *V. shilonii* primers non-specifically amplified background *E. coli* DNA forming a product well above the anticipated size (~2.5 kb). This product was easily discernible from the target amplicons.

Field Testing

Sixty seven samples were assayed from healthy and diseased acroporid corals at 6 sites from Biscayne National Park, Florida Keys National Marine Sanctuary, and Drt Torugas National Park during a 2003 acroporid mortality event (Williams and Miller 2005). The presence of three of the microbes (*A. coralicida, V. shilonii*, and *V. coralliilyticus*) were indicated in the coral sample set (no instances of *S. marcescens*), while none of the targets were detected in the samples from the surrounding seawater. Sampling location, coral species, sample type (mucus or fragment), and health state did not correlate with the occurrence of any of the microbes.

Acropora spp. corals were sampled at five sites surrounding the island of St. John (USVI) from healthy corals and those exhibiting signs consistent with white pox disease or white band disease. Positive results were obtained from *A. coralicida* and *S. marcescens* (Table 3). While these microbes were present in ten and seven samples respectively, no consistent associations were noted with either white band or white pox like disease states. Sampling location and coral species were also not linked to the occurrence of any of the microbes.

Samples were collected from 51 apparently healthy *Porites astreoides* colonies at eight sites near La Paguera, Puerto Rico. Results indicate the presence of each of the four target bacteria. *S. marcescens* was the most commonly detected, with six of seven colonies at one site (17.93ºN 66.94ºW) and three of six at an adjacent site (17.96ºN 67.02ºW) testing positive for this microbe.

Discussion

Primers were initially tested against a small number of known bacterial cultures, but the

sometimes crowded phylogenies and abundance of undescribed and/or unculturable phylogenetic neighbors made exhaustive specificity testing in this manner unwieldy and potentially incomplete. The model for testing used here relied on virtual hybridizations against sequences from the RDP and NCBI nucleotide databases, followed by application of the assays to numerous coral samples from multiple locations, dates, species, and health states. All amplicons were validated by DNA sequence analysis. In this manner, the primers were subjected to evaluation against a large number of environmentally relevant microorganisms.

The ability to exhaustively validate the specificity of the *Aurantimonas coralicida* primers is limited by a lack of suitable representatives of this relatively novel and poorly characterized genus (3 members) and candidate family (2 genera). Without a more extensive database of sequences from these taxa it is hard to determine specificity precisely, but based on sequencing of environmental amplicons it appears that only sequences with near 100% identity to the pathogenic strain are amplified using this primer set.

The *S. marcescens* primer set displayed a very high level of specificity, with multiple strains of *S. marcescens* inducing a positive result while no other species of *Serratia* were detected in samples. Identical sequences are deposited in GenBank for some strains of *S. marcescens* and the related species *Kluyvera ascorbata*. The phylogenetic relationships among genera of the family Enterobacteriaceae are poorly defined and overlap between genera has been reported (Pavan et al. 2005). There are no reports of *Kluyvera* spp. associated with any marine organism and only a single *Kluyvera* sp. sequence (DQ316136; unpublished) deposited in GenBank is noted to be from the marine environment (seawater from China), thus the likelihood of a non-specific identification of *K. ascorbata* in coral is exceedingly unlikely.

The genus *Vibrio* is highly subdivided, comprised of 88 species with standing in nomenclature (Euzéby 2009). There is much contention over the criteria used to divide related strains into separate species. Many have 99 to 100% homology over portions (and occasionally the full length) of the 16S rDNA. The issue of differentiating *Vibrio* spp. is further compounded by the sheer number of sequences deposited, the GenBank database contained 5,473 16S rDNA sequences annotated "*Vibrio"* (January 2009). Many of these clones were annotated based solely on similarity of 16s rDNA, thus many are likely misidentified at the species or even genus level. In addition there are countless unannotated clones that are likely *Vibrio* spp. These combined issues make the task of determining specificity among *Vibrio* specific primers very difficult.

Amplicons from *V. shilonii* and *V. coralliilyticus* primer sets produced sequences that were difficult to precisely place phylogenetically. These sequences did however show a high level of specificity, as only slight degeneracy in primer binding would have been expected to produce amplicons from every sample due to the ubiquitous nature of V*ibrio* spp. in the reef environment. These primers only detected sequences that would be expected based on 0 or 1 bp mismatch in the primer binding. It was noted that the *V. coralliilyticus* primers would occasionally amplify sequences homologous to those annotated as *V. shilonii* from environmental samples, but never from DNA extracted from stock cultures of *V. shilonii.* This could be due to some similarity to sequences of certain *V. shilonii* strains, but is very likely due to erroneous annotation of sequences in GenBank. The *V. shilonii* primers never produced amplicons homologous to *V. coralliilyticus* sequences, providing an avenue for detection of false-positives.

Qualitative identification of target microorganisms is classically subdivided into three types of nested tests: presumptive, confirmed, and completed (in order of increasing confidence) (Eaton et al. 1995). A positive result obtained by application of the assays presented here should not be viewed as proof that the target microbe is present. It rather demonstrates that the target bacterium, or one with very close sequence homology, occurs in the sample. Thus the PCR assay should be treated as a "presumptive test", with subsequent sequencing of amplicons acting as the complementary "confirmed test". This confirmed test can provide reasonable certainty that the target is present. The only "completed test" that can be offered is to isolate and characterize the target microbe, followed by laboratory infection studies.

Sensitivity assays indicate the lower detection limits of each assay exceeded 0.62 target cells/µl (620 cells/ml) within a relevant background concentration of approximately 1 x 10^3 non-target cells/µl (1 x 10^6 cells/ml), or 0.06% of the total. These sensitivity levels exceed what would likely be necessary to detect an active pathogen. For instance, *V. shilonii* has been shown to maintain populations in the coral mucus exceeding 1 x 10^6 cells/ml during an infection (Banin et al. 2000). Thus these assays provide detection of target bacteria at what are likely sub-infection levels.

The three case studies presented in this paper, illustrate potential utility of these assays. The 2003 mortality of acroporid corals along the Florida Reef Tract had disease signs, which displayed both differences and similarities to two "white disease", white pox (previously reported in *A. palmata*) and white plague (reported in a large number of non-acroporid species). The application of the primer sets

quickly excluded the previously published white plague and white pox pathogens. These results were later confirmed by extensive culturing and 16S rDNA library sequencing (Polson 2007).

A survey of healthy and diseased acroporid corals from the US Virgin Islands identified a number of both healthy and diseased corals that tested positive for the target microbes. The diseased corals in this sample collection had disease signs that fit the classical descriptions for white band and white pox disease. Interestingly, the white pox samples did not show any correlation with the presence of *S. marcescens*, the reported pathogen from the Florida Keys. This observation underlines the critical point that identical coral disease signs do not necessarily equate to identical etiologies. This survey represents the first confirmation of *Acropora palmata* exhibiting disease consistent with that described as white pox without the association of *S. marcescens.*.

Surveys of *Porites astreiodes* colonies along the southwest coast of Puerto Rico indicated the presence of all targeted microbes. In particular *Serratia marcescens* is noted to occur in approximately 25% of the corals sampled, with greater than 50% abundance at two of the sampling sites. *S. marcescens* is not known to produce disease in *P. astreoides*. While this observation is anecdotal, it does indicate that non-affected coral species may be a potential reservoir for this reported acroporid pathogen.

Each diagnostic primer set demonstrated potential for use in applications ranging from the diagnostic assessment of specific coral disease occurrences to more generalized surveillance of corals. Any application should be undertaken with the caveat that they represent an initial screening tool (a presumptive test) for the presence of target organisms. Despite this limitation, the assay allows for results to be obtained from a large number of samples in a relatively short period of time, quickly narrowing the number of samples on which more intensive investigation may be needed. The utilization of a standardized protocol (sampling, processing, and analysis) will allow data comparisons across laboratories, enabling the combination of disparate sample sets that would not normally be processed together, setting the stage for addressing large-scale questions.

Acknowledgement

The authors would like to thank C. Rogers and L. Sileo (USGS) for generously providing acroporid coral samples from the U.S. Virgin Islands National Park (permit VIIS-2004-SCI-0025 to CR). Thanks also to D. Williams, M. Miller, S. Ryan, M. Lundqvist, C. Fasano, R. Appulgliese,, R. Curry, D. Morrison, and W. Causey for assistance collecting samples in Biscayne NP (permit BISC-2003-SCI-0043 to MM), Florida Keys National Marine Sanctuary (permit FKNMS-2002-084-A1 to DW), and Dry Tortugas National Park (Park Superintendant's Blanket Permit). Thanks to A. S. Pait for providing samples from Puerto Rico. We appreciate the helpful comments on this manuscript provided by L. May, L. Adams, T. Bartlett, S. C. Polson, J. Shockey, and three anonymous reviewers. Abstract. Genetic comparison of Archaea associated with the surface mucus of corals from three genera, namely *Acanthastrea* sp., *Favia* sp. and *Fungia* sp. from the Gulf of Eilat, Israel and from Heron Island, Australia were studied. Sequencing of the 16S rRNA gene of the coral-associated microorganisms revealed dominance of Crenarchaeota (79%, on average). In this phylum, 87% of the sequences were similar (≥97%) to the Thermoprotei, with 76% of these being similar (≥97%) to the ammonium oxidizer, *Nitrosopumilus maritimus*. Analysis of archaeal *amoA* sequences obtained from the fungiid coral, *Fungia granulosa*, divided into three clades, all related to archaeal sequences previously obtained from the marine environment. These sequences were distantly related to *amoA* sequences previously found in association with other coral species. Preliminary experiments suggest that there is active oxidiation of ammonia to nitrite in the mucus of *F. granulosa*. Thus, coral-associated Archaea may contribute to nitrogen recycling in the holobiont, presumably by acting as a nutritional sink for excess ammonium trapped in the mucus layer, through nitrification processes.

Key words: Archaea, ammonia, *amoA*.

Introduction

Coral reefs develop in oligotrophic marine environments. The surface of scleractinian corals, the main reef builders, is covered by a layer of mucopolysaccharides. This mucus layer is made up of a gel consisting of an insoluble hydrated glycoprotein (Brown and Bythell 2005) that is constantly secreted by the coral tissue. At the point of contact of the mucus with the surrounding water, a boundary layer is formed (Segel and Ducklow 1982; Ritchie and Smith 2004). Recent research has demonstrated that corals contain large, diverse and specific populations of microorganisms, including Viruses, Bacteria, Archaea, fungi, algae and protozoa that apparently co-evolved with corals (reviewed by Rosenberg et al., 2007). The presence of archaeal groups in association with corals has been reported (Wegley et al. 2004; Kellogg 2004), although the roles assumed by the Archaea in the coral holobiont have not yet been studied.

Archaea comprise four phyla, namely the Crenarchaeota, Euryarchaeota, Korarchaeota, and Nanoarchaeota. In the ocean, planktonic Crenarchaeota are most abundant (Fuhrman 1992; Karner et al. 2001). Although Crenarchaeota constitute about 20% of the total marine picoplankton biomass world-wide (Karner et al. 2001), their roles in the marine biogeochemical cycle have not been thoroughly explored (Wuchter et al. 2006). Until recently, Archaea were considered to be uncommon partners for invertebrate symbioses. Archaea were found in association with sponge species (Preston et al. 1996; Webster et al. 2001; Pape et al. 2006), although the ecological functions assumed by these sponge-linked microorganisms remain unknown.

Wegley et al. (2004) showed by fluorescent in situ hybridization (FISH) that Archaea on the coral, *Porites astreoides*, accounted for nearly half of the prokaryotic community, implying that Archaea are abundant, diverse, and potentially important components of the coral holobiont.

Corals obtain and assimilate nitrogen through predation (Piniak et al. 2003). Additional nitrogen can be obtained through direct absorption from the surrounding water (Muscatine and D'Elia, 1978; Badgley et al., 2006), by integration via associated microorganisms, such as nitrogen-fixing cyanobacteria (Lesser et al. 2004), and from microorganisms trapped in the coral mucus (Wild et al. 2004). Nitrogen metabolized by the corals leads to the production of ammonia that can be excreted into the environment.

Aerobic oxidation of ammonia by some microorganisms is catalyzed by ammonia

monooxygenase (AMO), an enzyme that converts ammonia to hydroxylamine, which is further converted to nitrite by hydroxylamine oxidoreductase (Nicol and Schleper 2006). A time series study in the North Sea revealed that the abundance of archaeal *amoA* was 1 to 2 orders of magnitude higher than those of *amoA* from nitrifying bacteria. Sea water incubated with ammonia was dominated by a single member of the crenarchaeotal phylogenetic cluster showing 99% sequence identity over the nearly complete 16S rRNA gene of the nitrifying Crenarchaeote, *Nitrosopumilus maritimus* (Wuchter et al. 2006). *N. maritimus* is a marine chemolithtotroph which aerobically oxidizes ammonia to nitrite with near stoichiometric conversion, using ammonia as its sole energy source (Könneke et al. 2005).

Wafar et al. (1990) suggested that nitrification occurs at significant rates in living coral colonies. The authors showed that nitrifying coral-associated microorganisms can vary from 4 to 260 x 10^3 cells per mg coral tissue. Recently putative archaeal *amoA* genes encoding ammonia monooxygenase subunit A were retrieved from several corals (Beman et al. 2007). Indeed, while archaeal *amoA* sequences were obtained from different species of coral-associated Archaea, no bacterial *amoA* sequence could be amplified from any of these samples.

In this report, we study coral-associated Archaea from three genera of corals (*Acanthastrea* sp., *Favia* sp. and *Fungia* sp.) from the Red Sea, Israel with those from Heron Island, Australia concentrating in Crenarchaeota. Based on our findings, the possible role of coral-associated Archaea in the coral holobiont is discussed.

Material and Methods

Samples of the hermatypic corals, *Fungia* sp., *Favia* sp. and *Acanthastrea* sp., were collected at depths of 5-10 m at Heron Island GBR Australia (23º26 'S, 151°54 'E), in July, 2006, and near the Inter-University Institute for Marine Science in the Gulf of Eilat (29°51 'N, 34°94 'E), Red-Sea, in June, 2007. Within one hour of collection, the corals were placed in aquaria filled with running sea water. On the same day, mucus was sampled from the corals using sterile bacteriological loops. Sea water from Eilat was collected by opening a sterile container on the same dives. Four additional *Fungia granulosa* individuals were collected in December, 2007 for mucus collection, for NO_2 production experiments. This was carried out by inverting the corals on a funnel for 2 min. Mucus for DNA extraction was sampled from two of the *F. granulosa* corals using bacteriological loops, as previously described (Barneah et al. 2007).

F. granulosa mucus (2 ml) was filtered through 0.1 μm filter. The filters were then placed in glass flasks with 10 ml sterile sea water and 1mM ammonium chloride at 22-25ºC and incubated with shaking for up to 28 days. Since streptomycin inhibits the growth of nitrifying bacteria (Könneke et al. 2005), to eliminate the activities of bacterial ammonia oxidation, two flasks were incubated with 500 mg L^{-1} of streptomycin. Eight milliliters of filtered mucus topped with 2 ml sterile sea water containing 1 mM ammonium chloride served as control. NO_2 was measured after 0, 2, 15 and 28 days, according to standard methods for the examination of water and wastewater (Clesceri et al. 1998).

Genomic DNA from the mucus samples was extracted by a PowerSoil purification kit (Mo Bio Laboratories Solana Beach, CA. USA), and stored at -20°C. To extract genomic DNA from the water column, 2 L of sea water collected from the same depths were passed through sterile 0.2 μm filters and the DNA was extracted as above. Total DNA was PCR-amplified using specific archaeal 16S rRNA gene modified primers; Arch-21F (5'-TTCCGGTTG ATCCYGCCG-3'), obtained from DeLong (1992) and Arch-915R (5'-GTGCTCCCCCGCCAATTC-3'), taken from Amann et al., (1995). An initial denaturing step of 4 min at 95°C was followed by 30 cycles of the following program pattern: 94°C for 30 sec, 54°C for 30 sec, and 72°C for 70 sec. The procedure was completed with a final elongation step at 72°C for 30 minutes. Archaeal *amoA* gene fragments were amplified using Arch-amoA-F (5'-STAATGGTCTGGCTTAGACG-3') and Arch-amoA-R (5'-GCGGCCATCCATCTGT ATGT-3') primers and conditions as previously described (Francis et al. 2007; Beman et al. 2007).

The gel-purified PCR products were cloned into the PCRII-TOPO- A cloning vector, as specified by Invitrogen (Carlsbad, CA) and transformed into calcium chloride-competent *Escherichia coli* HD5a cells. More than 50 clones from each sample were amplified using M13-F and M13-R primers and sequenced, using the Arch-21F primer. All sequences were first compared with those in the GenBank database with the basic local alignment search tool (BLAST) network and check for chimeric sequences using Bellerophon (Huber et al. 2004).

Results

A total of 424 clones derived from 8 coral samples (>50 clones from each library) displayed a prevalence of crenarchaeotal sequences (79%), as compared to euryarchaeotal sequences (21%) (Fig. 1). Red-Sea water displayed opposite prevalence with dominants of Euryarchaeota (63%).

BLAST analysis revealed that of the coral-drived crenarchaeotal sequences, 87% were similar (≥97%) to the class Thermoprotei. Of this group, 76% were

similar (≥97%) to sequence of *Nitrosopumilus maritimus* (DQ085097) (Fig. 1), a marine Archaea that oxidizes ammonia Könneke et al., (2005).

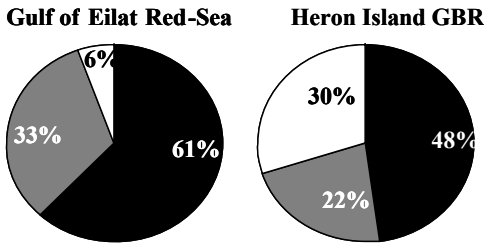

Fig. 1: Archaea distribution by sample location. Crenarchaeota similar to *Nitrosopumilus maritimus* (≥97%, FastGroup II) (black), other Crenarchaeota (gray) and Euryarchaeota (white).

Analysis of the archaeal *amoA* from two *F. granulosa* corals, Rs-Fg1 and Rs-Fg2 (24 sequences in each clone library), collected from the Red Sea, yielded three different clades, all related to sequences retrieved from the marine environment. Part of the nitrification cycle of the mucus-associated microorganisms was demonstrated by nitrite production.

Nitrification measurements of *F. granulosa* mucus-derived microbiota incubated with 1 mM ammonia revealed an increase of 50% after 15 days and a 9-fold increase after 28 days (Table 1). Production of nitrite after 28 days of incubation in a streptomycin-amended medium (designed to inhibit nitrifying bacteria) was slightly lower than in non streptomycin-amended samples.

Table1: NO_2 production by *F. granulosa* coral mucus-associated microorganisms during 28 days.

Days NO_2 (ppm)	0	2	15	28
Control	0	0	0.037	0.096
Coral mucus microorganisms	0	0	0.1186	1.076
Coral mucus microorganisms + streptomycin	0	0	0.118	0.856

Discussion

Phylogenetic analysis of archaeal 16S rRNA gene sequences retrieved from three corals species from the Red Sea (*Fungia* sp., *Favia* sp. and *Acanthastrea* sp.) displayed high similarity (up to 100%) to archaeal sequences retrieved from the same coral genera from the GBR. 67% of the 424 sequences from those locations were closely related (≥97%) to sequences derived from three scleractinian corals from the Virgin Islands (Kellogg 2004), implying the existence of a general coral-archaeal symbiotic association.

In general, the Crenarchaeota sequences were most abundant in coral samples from the Red Sea than in GBR (Fig. 1). A higher abundance of Crenarchaeota (73%) over Euryarcaeota (27%) was also observed by Wegley et al. (2004). By contrast, Kellogg (2004) reported a dominance of Euryarcaeota (average of 80%) in scleractinian corals from Carribian. This may a biogeographic distinction, or due to differences in sample collection methods.

The prevalence of Euryarchaeota over Crenarchaeota in the sea water sample was previously reported with water samples from oceanic photic zones (Delong et al. 2006; Delong 2007). This result strengthens the premise that conditions in the mucus differ from those in the surrounding medium.

Interestingly, almost all (87%) coral Crenarchaeota sequences analysed by BLAST were most closely related (≥97%) to the Thermoprotei class and 76% of these sequences were highly similar (≥97%) to that of *Nitrosopumilus maritimus* (DQ085097), whereas only 27% of the sea water-associated archaeal clone library sequences were similar to this strain. *N. maritimus*, isolated from the rocky substratum of a tropical marine tank, is an autotrophic crenarchaeote that is able to obtain its energy by oxidizing ammonium, producing nitrite as the end product (Könneke et al. 2005; Delong 2007). Positive correlations between the abundance of Crenarchaeota and ambient nitrite concentrations were observed in the Arabian Sea (Sinninghe et al. 2002) and in Santa Barbara (Murray et al. 1999). It is possible that the coral mucus layer is rich in ammonium and other metabolic by-products of corals, providing a rich nutritive source for these microorganisms.

Though ammonium can be utilized by coral zooxanthellae, very high levels may be detrimental to the coral holobiont. This may be due to the fact that high ammonium levels cause an inhibition of carbohydrate assimilation by algae (Azov and Goldman 1982) or affect other metabolic parameters, such as an inhibition of nitrate uptake (Badgley et al., 2006). It is feasible that mucus-associated Archaea act in the coral holobiont as a sink for excess ammonia, recycling it through nitrification during the day, when oxygen is in excess due to photosynthesis of the zooxanthella symbionts.

I this study we, screen the archaeal *amoA* gene in the Red Sea *Fungia* sp. Results showed that coral-associated archaeal *amoA* genes clustered into three clades, all related to sequences obtained from the marine environment. Surprisingly, *amoA* genes of coral-associated Archaea from Bermuda (Beman et al., 2007) and the *amoA* gene of *N. maritimus* created a separate cluster with very low similarity (79%-85%) to the *amoA* sequences from our coral-associated

Archaea .This may be due to the fact that Archaea from the Bermuda were from corals that were not in as close association to the substrate as the Red Sea fungiids. On the other hand, most of our Crenarchaeota 16S rRNA gene sequences were closely related (≥97%) to *N. maritimus*. These differences may be explained by the choice of genes for comparison, namely the highly conserved 16S rRNA gene (Gutell et al., 1994) and the functional and variable *amoA* gene.

The 16S rRNA gene library of coral-associated Archaea showed that at least 50% of the clones were similar (≥97%) to ammonium oxidizer, *N. maritimus*. To further confirm the presence of ammonia oxidizing Archaea, NO_2 production by coral mucus microorganisms was investigated (Table 1) using streptomycin, an antibiotic that affects Bacteria but not Archaea (Könneke et al., 2005). Results showed an increase in nitrification in the mucus of *F. granulosa* throughout the experiment. Moreover, there was only a slightly lower production of nitrite after 28 days of incubation in a streptomycin-amended medium, as opposed to non-amended samples. These results provide evidence for the possible widespread presence of ammonia oxidizers in coral reefs. Similarly, Wuchter et al., (2006) showed that the addition of nutrients to North Sea water was followed by an enrichment of Crenarchaeota and was correlated with the concomitant decrease of ammonia and increase of nitrite concentrations.

Nutrients from the environment have to move across a physical boundary layer, as well as through the mucus layer, to reach the coral tissue. Nutrients from the coral tissue must pass an opposite route to reach the environment. Such movement of nutrients is governed by a very slow diffusion rate (Segel and Ducklow, 1982). It is likely that a microbe growing on the mucus surface has access to dissolved nutrients before the coral does and, conversely, has access to coral-borne nutrients before the planktonic microorganism population does. Therefore, the coral mucus may be a better living substrate for ammonia-oxidizing Archaea than the water column because these Archaea would encounter ammonia before planktonic organisms and at higher concentrations.

We, therefore, suggest the following role for mucus-associated Archaea in the coral holobiont nitrogen cycle. During the day, the mucus conditions are oxic, and Archaea similar to *N. maritimus* oxidize ammonia to nitrite, which may be assimilated into the coral. At night, the mucus conditions are anoxic and microorganisms, like the archaeal H. salifodinae, may convert nitrite into nitrogen via denitrification pathways. This implies that Archaea play an essential role in coral reef and coral holobiont physiology.

Abstract. In the oligotrophic marine environment there are ecological niches rich in nutrients and diverse in bacterial populations. One such niche is the coral surface mucus layer. Interactions amongst microorganisms found in coral mucus may be symbiotic or competitive; competing over space and food. It has been hypothesized that the microbial communities found on the coral surface may play a role in the coral's defense, possibly through the production of antimicrobial substances. To find potentially active compounds produced by coral-mucus bacteria, over 200 selected microorganisms isolated from the mucus layer of a number of coral species were grown using agar plating technique. Screening for antibacterial substances was performed using overlay and drop techniques, and antibacterial activity was tested against indicator microorganisms. Results indicate that more than 20% of cultivable mucus-associated bacteria originating from hard corals demonstrated antibacterial activity. Isolates obtained from hard corals demonstrated higher percentage of activity than soft corals' isolates. Isolates related to the genera *Vibrio* and *Pseudoalteromonas* demonstrated high activity against both gram-positive and gram-negative bacteria. These results demonstrate the existence of microorganisms with antibacterial activity on the coral surface, indicating that they may play a role in protecting the coral host against pathogens.

Key words: Antibacterial activity, Coral mucus, Mucus-associated bacteria.

Introduction

The coral mucus layer serves as an ecological niche rich in nutrients and diverse in bacterial populations. However, the exact role of these microorganisms in the coral holobiont is yet to be determined. Such interactions may be symbiotic or competitive; competing over space and food. Rohwer et al. (2002) hypothesized that the microbial community found on a coral's surface may play a role in the coral's defense mechanism, possibly by occupying niches or through the production of antimicrobial metabolites.

Various studies have reported antimicrobial activity of extracts from marine organisms such as sponges (Kelman et al. 2001), soft corals (Harder et al. 2003, Kelman et al. 1998) and scleractinian corals (Geffen and Rosenberg 2005, Koh 1997). Kelman et al. (2006) reported that the majority of extracts from six soft corals demonstrated high antimicrobial activity against marine bacteria isolated from surrounding seawater, as opposed to extracts from six stony corals exhibiting little or no antimicrobial activity. Ritchie (2006) found that 20% of cultured bacteria from the mucus layer of the coral *Acropora palmata* displayed antimicrobial activity, and that a novel mucus-mediated medium was found to be selective for isolates that produce antibiotics. Thus, the presence of microbial populations on the mucus surface of various invertebrates may play a part in their defense strategy.

Material and Methods

Samples were collected from coral mucus layer, as well as from sea water and sediment around the corals, from the Gulf of Eilat. Among coral samples collected were seven hard corals (*Platygyra sp.*, *Porites sp.*, *Fungia granulosa*, *Favia sp.*, *Stylophora sp., Pocillopora sp.* and *Turbinaria sp.*) and two soft corals (*Rhytisma fulvum fulvum* and *Xenia sp.*). Mucus samples were collected from apparently healthy corals from the upper portion of the coral colony or polyp, and the collection procedure was carried out as described previously by Barneah et al. (2007). Serial dilutions were performed using autoclaved artificial sea water followed by spreading over marine agar plates at 50% and 10% concentrations.

Isolates were screened for antibacterial activity using two techniques: overlay with soft agar and drop technique. Screening was performed against common indicator bacteria, including *Bacillus cereus*, *Escherichia coli*, *Serratia marcescens* and *Staphylococcus aureus*, as well as the marine pathogen *Vibrio coralliilyticus*. The first method is a modification of the overlay technique described by Geis et al. (1983), and involved pouring soft agar mixed with indicator bacteria over marine agar plates containing 5-week old colonies of marine isolates from coral mucus. For this method, only *B. cereus*

and *E. coli* served as indicator bacteria. Antibacterial activity was defined by measuring the radius of the inhibition zone of the growth of indicator bacteria around the colony after 12 hours of incubation. The drop technique involved incubation of marine isolates in 100% marine broth for 72 hours at 26°C with agitation (120 rpm). After sufficient growth, 10 µl of the marine isolates were placed on agar plates containing 120 µl of an overnight culture of indicator bacteria spread as a lawn, followed by incubation for 12 hours at the optimal temperature for that indicator. Isolates obtained from sea water and sediment were used as negative controls for antibacterial screening, using the drop technique. Supernatant, produced by filtration of marine isolate cultures through sterile 0.2 µm filters, was also tested for antibacterial activity using this technique. Activity was detected by the formation of an inhibition zone where the drop was placed, and recorded qualitatively based on degree of transparency.

Isolates' DNA was extracted and 16S rRNA gene fragments were PCR amplified using 8f and 1512r primers. Sequences were then compared with the GeneBank database (NCBI Blast), and a Phylogenetic analysis was performed using MEGA 3.1 software.

Results

Over 20% of cultivable bacteria isolated from mucus demonstrated activity against indicator bacteria. Seventy eight isolates originating from hard corals were screened for antibacterial activity using the overlay technique. Nineteen of these isolates (24.3%) demonstrated activity against indicator bacteria. The percentage of active isolates from each coral species, as determined using the overlay technique, is presented in Fig. 1. The highest percentage of active isolates originated from *Pocillopora sp.* and *Platygyra sp.* (44% and 38%, respectively).

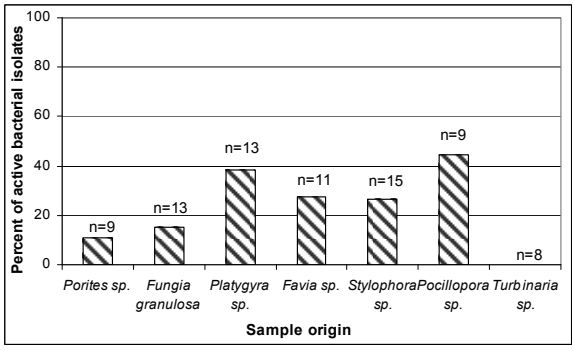

Figure 1: Percentage of active isolates obtained from hard corals. Antibacterial activity was detected using the overlay technique as described in Materials and Methods. n = number of screened bacterial isolates.

146 isolates from soft and hard corals, as well as sea water and sediment, were screened for antibacterial activity using the drop technique. Out of 84 isolates originating exclusively from hard corals, 21 (25%) demonstrated antibacterial activity. However, among 22 isolates obtained from soft corals, only 3 (13.6%) were found to be active. Sediment isolates did not show any antibacterial activity, while only one out of 14 (7%) sea water isolates was found to be active (see Fig. 2). The highest percentage of active isolates originated from *Favia sp.* (42%).

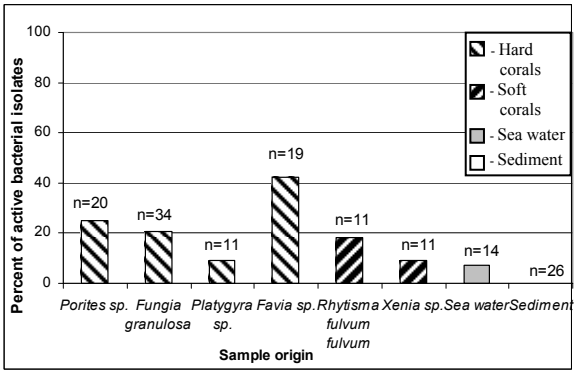

Figure 2: Percentage of active isolates obtained from hard and soft corals, sea water and sediment. Antibacterial activity was detected using the overlay technique as described in Materials and Methods. n = number of screened bacterial isolates.

16S rRNA genes of 46 isolates were sequenced and compared to the NCBI Genebank database. Thirty-eight out of these isolates demonstrated antibacterial activity using either of the screening techniques. Most of the isolates belonged to the *γ-proteobacteria* class (78%), while the rest belonged to the *Firmicutes* (15%) and *Actinomycetales* (7%) phyla. Amongst the *proteobacteria*, isolates related to the genera *Vibrio* and *Pseudoalteromonas* were the most abundant and demonstrated high activity against both gram-positive and gram-negative bacteria.

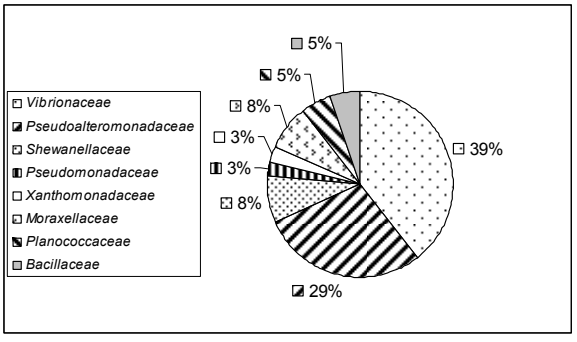

Figure 3: Percent of active isolates from total active isolates sequenced, distributed to each family taxa.

Isolates related to the genera *Shewanella* and *Acinetobacter* only demonstrated activity against gram-positive indicator bacteria. Gram-positive isolates (*Bacillus*, *Planomicrobium*) demonstrated

lower activity, primarily against other gram-positive bacteria. The distribution of active isolates sequenced according to family taxa is presented in Fig. 3.

Discussion

This study tested for antibacterial activity among cultivable coral mucus-associated bacteria and demonstrated that 20-25% of coral mucus cultivable bacteria display antibacterial activity.

Over 230 bacterial isolates obtained from the marine environment of the Gulf of Eilat were screened for antibacterial activity. In general, coral mucus-associated bacteria demonstrated a higher percentage of activity than sea water or sediment isolates. Antibacterial activity detected in isolates originating from hard corals was higher than activity demonstrated by soft coral isolates (25% and 13.64%, respectively). Sea water and sediment isolates demonstrated little or no antibacterial activity.

These results are in agreement with the findings presented by Ritchie (2006), according to which 20% of cultivable bacteria obtained from the mucus layer of the coral *Acropora palmata* demonstrated antimicrobial activity against indicator bacteria. According to Kelman et al. (2006), soft coral extracts were found to be more active than hard coral extracts. The authors also suggested that there are different mechanisms of antimicrobial activity against pathogens involved in scleractinian corals. This also may suggest that production and secretion of antimicrobial compounds by mucus-associated bacteria is part of the scleractinian coral's defense strategy against pathogens (Rohwer et al. 2002; Ritchie 2006; Reshef et al. 2006).

$\delta^{13}C$ and $\delta^{15}N$ values for branching corals in the Berau Marine Conservation Area in East Kalimantan, Indonesia

H. A. Susanto[1], M. Yoneda[1,2], H. Koike[1]

1) Kyushu University, Dept. of Environmental Changes, 4-2-1 Ropponmatsu, Chuo-ku, Fukuoka, Japan
2) Japan Wildlife Research Center, 3-10-10 Shitaya, Taito-ku, Tokyo, Japan

Abstract. Carbon and nitrogen isotope ($\delta^{13}C$ and $\delta^{15}N$) values in coral tissue and zooxanthellae of the coral reef species *Porites sp., Seriotophora sp.* and *Stylophora sp.* from the Berau Marine Conservation Area, East Kalimantan, Indonesia were measured. Coral samples were collected during both the dry season (August 2006) and the rainy season (November 2007). Most of the $\delta^{15}N$ values of the coral tissue during the dry season were heavier than those of the zooxanthellae. This result indicates that the zooxanthellae must be the main nutrient source for the coral tissue. However, the majority of $\delta^{15}N$ values for the coral tissues during the rainy season had similar or even lighter values than those of the zooxanthellae, suggesting that during the rainy season corals also utilize particulate organic matter (POM) as a food source.

Key words: $\delta^{13}C$, $\delta^{15}N$, coral tissue, zooxanthellae, particulate organic matter (POM)

Introduction

The Berau Marine Conservation Area (MCA), East Kalimantan, Indonesia has the third highest coral diversity (507 species) in the world (Turak 2003). This area, which consists of 31 islands, is an important coral habitat and a part of the Coral Triangle, the center of tropical marine fish and invertebrate biodiversity. The Berau MCA is also known as the largest rookery for the green turtle in Southeast Asia and a manta ray habitat, as well as including the unique Kakaban Lake with its stingless jellyfish (Wiryawan et al. 2005).

Currently, coral reefs in the Berau MCA are under stress from the combined impact of human exploitation, physical disturbance, pollution, and increased sediment (Turak 2003; Wiryawan et al. 2005). Conversion of mangrove forest to shrimp ponds in the estuary areas, coal mining and loading along the Berau river, and conversion of land for agricultural use and logging in the highlands have been occurring for a long time. All of these human activities could lead to higher sediment loads in the Berau river and ultimately affect the condition of the reefs, especially those located nearest the river mouth.

Data from the EU's Berau Forest Management Project (BFMP, Obidzinski and Andrianto 2005) noted that during 3 years (1997-2000), Berau lost approximately 127,500 ha of forest. In the following six years, from 2000 to 2006, Berau lost 41.1% of protected forest (353,775 ha in 2000 to 208,374 ha in 2006); while fixed forest production decreased from 758,049 ha to 589,567 ha, a reduction of 22.2% (Anonymous 2007). All this deforestation, from both legal and illegal logging activities, has a tremendous big impact on the condition of soil and water resources (Obidzinski and Andrianto, 2005).

The average river discharge is approximately 1,200 m^3/s into the coastal waters. The sediment concentration in the river water was 50 mg/l on average and Buschman (2007) estimated that for every year approximately 2 metric tons of sediment are exported to the Berau coastal area.

The main objective of this study is to understand the effects of the sediment discharge on the condition of the coral reef using $\delta^{13}C$ and $\delta^{15}N$ analysis. Analysis of $\delta^{13}C$ and $\delta^{15}N$ have been successfully used to trace the input of organic matter, assuming that the $\delta^{13}C$ of the consumer is correlated with the $\delta^{13}C$ of their diet and that the $\delta^{15}N$ value of the consumer is heavier than the $\delta^{15}N$ value of their diet (Peterson and Fry, 1987, Yamamuro and Kayanne, 1995)

All reef-building hard corals contain zooxanthellae which live symbiotically within the tissue of the corals and provide energy and nutrients. Generally, coral animals obtain most of their nutrients from the zooxanthellae, causing the $\delta^{15}N$ value of the coral to be heavier than the zooxanthellae. However, in turbid water conditions, the zooxanthellae may fail to provide enough nutrients due to a turbidity dependent reduction in products of photosynthesis, resulting in a change in the relative $\delta^{13}C$ and $\delta^{15}N$ values for the coral and zooxanthellae. In this study, we compared isotopic values of zooxanthellae and

coral tissue collected from high sedimentation coastal areas and clear water offshore areas at two different seasons and depths.

Materials and Methods

Coral samples were collected both during the dry season, in August 2006, and the rainy season, in November 2007, from three sites, designated Locality-1 (nearest the Berau River mouth at the Rabu-rabu and Panjang Islands), Locality-2 (an intermediate distance from the river mouth, at Derawan Island), and Locality-3 (farthest from the river mouth, at the Semama and Sangalaki Islands) (Fig.1-A and B). Samples were collected at two different depths, 3 meters and 10 meters.

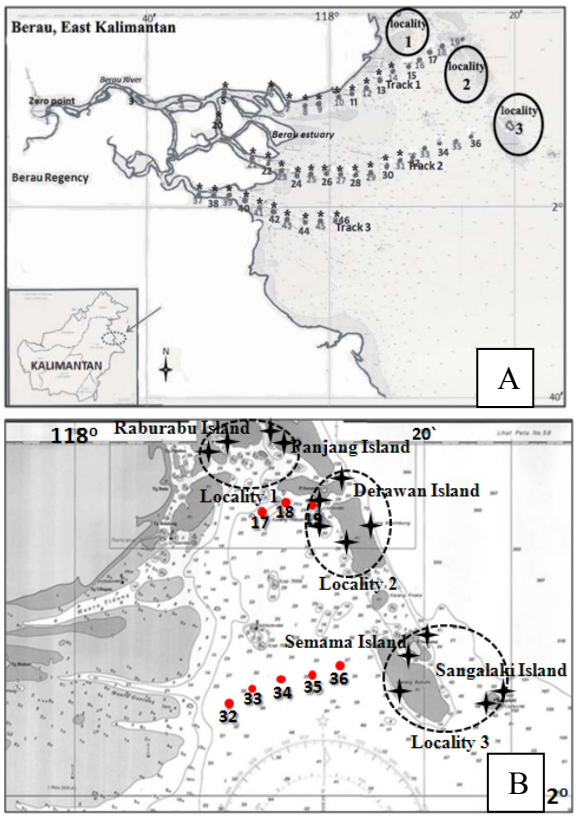

Figure 1. (A) Map of the study area showing the sampling points for sediment and plankton along track 1, track 2, and track 3. (B) Map of coral reef sampling areas at Locality 1, Locality 2, and Locality 3. ✦ indicates a dive point.

Zooxanthellae were separated using a standard ethanol and sonication method. Coral samples were treated with an ultrasonic generator for 10 min and centrifuged at 3000 rpm for 10 min (Piniak and Lipschultz 2004). The resulting pellet of zooxanthella was decalcified using HCl to remove any carbonates and then rinsed twice with DDW. Coral tissue was obtained by decalcification method. Sample was ground into coarse fragments and placed in a cellulose tube. The tube was placed in a beaker containing 0.2 N HCl on a stirrer (Horai et al. 1989). Decalcified zooxanthellae and the tissue were then centrifuged and freeze-dried overnight.

In addition, water parameters such as salinity, temperature, turbidity, pH, and dissolved oxygen (DO) were monitored using a Water Quality Checker (Horiba) along three track lines, track 1, track 2, and track 3 representing the northern, middle, and southern parts of the river effluent, respectively. Water parameters were also measured near the coral reefs (Fig.1). Bulk Particulate Organic Matter (POM) samples were collected from surface water using plankton nets with 100 µm and 310 µm mesh sizes. POM was centrifuged at 2500 rpm. The resulting pellet was decalcified by HCl treatment, rinsed twice, and freeze-dried overnight. Zooplanktons were disaggregated from the POM samples using a binocular. Aliquots (0.8±0.05 mg) of all samples were placed in tin capsules for isotopic measurements.

A total of 132 coral reef and 160 POM samples were measured using an ANCA mass spectrometer. The $\delta^{13}C$ and $\delta^{15}N$ values are expressed in ‰ as defined by the following equation:

$\delta^{13}C$ or $\delta^{15}N$ (‰) = $(R_{sample}/R_{standard} - 1) \times 10^3$

where $R = {}^{13}C/{}^{12}C$ or ${}^{15}N/{}^{14}N$. Measurement errors were 0.1‰ for $\delta^{13}C$ and 0.3‰ for $\delta^{15}N$ and data are reported relative to Pee Dee Belemnite (PDB) and Air standards, respectively.

Results and Discussion

Water quality tests

The water salinity ranged from 32.5±1.4‰ in the rainy season to 35.8±0.8‰ in the dry season. The average salinity at the bottom of the water column was slightly higher than the surface water salinity in both seasons. Turbidity values (Table 1) measured in Locality 1 were higher than all others.

Table 1. Average water parameters at the reef areas.

Locality	Dry season (Aug 2006)		Rainy season (Nov 2007)	
	surface	bottom	surface	bottom
Turbidity (NTUs)				
Locality 1	0.8±1.0	2.5±2.5	1.5±1.3	2.5±2.6
Locality 2	0	0.3±0.5	0	0.5±1.0
Locality 3	0	0	n.d	n.d
pH				
Locality 1	8.4±0.1	8.4±0.0	8.0±0.1	7.9±0.0
Locality 2	8.4±0.1	8.4±0.1	8.0±0.0	8.0±0.0
Locality 3	8.4±0.1	8.4±0.1	n.d	n.d
DO (mg/l)				
Locality 1	6.3±0.2	6.4±0.1	5.5±0.0	5.5±0.0
Locality 2	6.7±0.9	6.8±0.9	5.7±0.1	5.6±0.1
Locality 3	6.8±1.2	6.8±1.1	n.d	n.d

Turbidity at Locality 1 was slightly higher during the rainy season than in the dry season, which may have

been the result of heavy rainfall and higher river discharge, and, consequently, pH and DO values were lower in the rainy season.

These results correspond to the difference between the average rainfall rate during the dry season of August 2006 (83.7 mm) and the rainy season of November 2007 (235.8 mm) (Anonymous 2008).

δ¹³C and δ¹⁵N of coral tissue and POM

The range of $\delta^{13}C$ and $\delta^{15}N$ values of coral tissue and zooxanthellae from three branching coral reefs are shown in Fig. 2. The average $\delta^{13}C$ values of coral tissue and zooxanthellae of the *Porites sp.* were less negative than those of *Stylophora sp.* and *Seriotophora sp.*. The average $\delta^{15}N$ values for coral tissue in all the branching corals was always heavier than those of the zooxanthellae. However, analysis of variance revealed that there were no significant differences in $\delta^{15}N$ value among species ($p > 0.05$).

The average $\delta^{13}C$ value of POM near the coral reefs was -18.5±1.3‰. The average $\delta^{13}C$ value of POM during the dry season (-18.6±0.8‰) was slightly lighter than during the rainy season (-18.4±1.6‰). Almost all $\delta^{13}C$ values of POM depend on the marine planktonic organic carbon (-19.5‰; Chisholm and Koike, 1996) rather than the coral ecosystem (-12 to -13‰; Muscatine et al. 1989).

$\delta^{15}N$ values of POM ranged from 0.9‰ to 6.3‰ with an average of 4.2±1.6‰. The average $\delta^{15}N$ value during the dry season (5.5±0.9‰) was heavier than during the rainy season (3.3±1.4‰). The shift in $\delta^{15}N$ values of POM at each locality is shown in Fig. 2. The decrease in $\delta^{15}N$ value of POM during the rainy season may be caused by denitrification processes which can reduce $\delta^{15}N$ values by 20-30% (Montoya 2007).

As shown in Fig. 2, the average $\delta^{15}N$ values of POM during the rainy season at each locality more depleted than those collected during the dry season. Hence, $\delta^{15}N$ values of POM during dry season were heavier than $\delta^{15}N$ values of coral tissue. In contrast, $\delta^{15}N$ values of POM during the rainy season were lighter than $\delta^{15}N$ values the coral tissue, which may reflect an increase in primary production

δ¹³C and δ¹⁵N values differ with depth

Muscatine and Kaplan (1994) noted that the $\delta^{13}C$ and $\delta^{15}N$ values of zooxanthellae and coral tissue generally become more depleted in most species with increasing depth. Our data (Fig. 3) exhibited a similar trend between samples collected at a depth of 3 m or 10 m, but there were no significant differences in isotopic values.

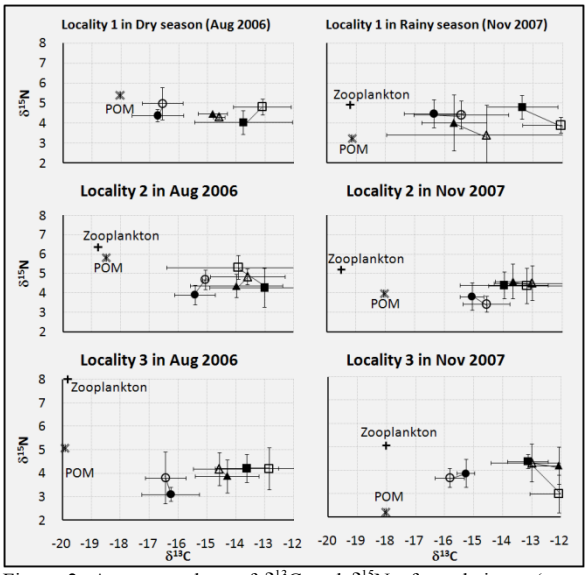

Figure 2. Average values of $\delta^{13}C$ and $\delta^{15}N$ of coral tissue (open symbols), zooxanthellae (filled symbols), and POM and zooplankton at each locality during the dry season (August 2006) and the rainy season (November 2007). □ *Stylophora sp.* ○*Seriotopora sp.* △ *Porites sp.*

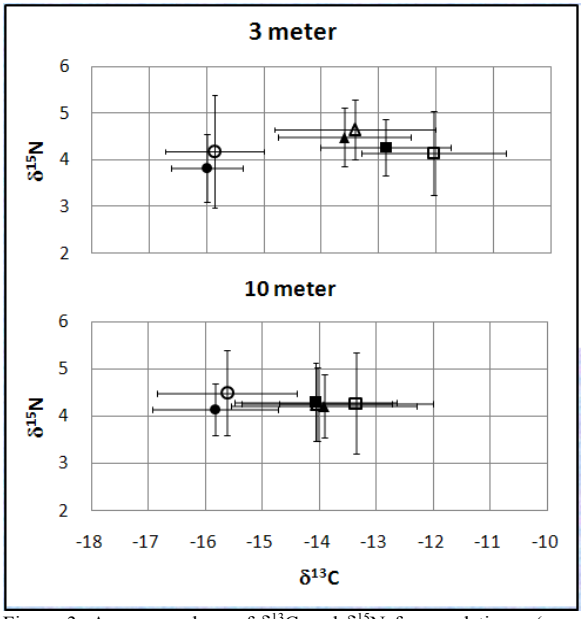

Figure 3. Average values of $\delta^{13}C$ and $\delta^{15}N$ for coral tissue (open symbol) and zooxanthellae (filled symbol) at a depth of 3 meters and 10 meters. □ *Stylophora sp.* ○*Seriotopora sp.* △ *Porites sp.*

δ¹⁵N differences between coral tissue and zooxanthellae

During the dry season, the average $\delta^{15}N$ value for coral tissues was 4.8±0.7‰ and that for zooxanthellae was 4.2±0.6‰. During the rainy season, the average $\delta^{15}N$ values of coral tissues and zooxanthellae were 4.1±1.0‰ and 4.4±0.7‰, respectively.

The $\delta^{15}N$ values of consumer tissues are known to correlate with their diet. The $\delta^{15}N$ values are observed to increase with increasing trophic level. The $\delta^{15}N$ difference between coral tissue and zooxanthellae indicates that the zooxanthellae play a role in providing nutrients to the coral. During the dry season, most of the coral tissue samples had $\delta^{15}N$ values that were heavier than those of the zooxanthellae. This result indicates that the zooxanthellae must be the main source of nutrients for the coral. However, measurement of samples collected during the rainy season revealed that the $\delta^{15}N$ values of the corals were not always heavier than those of the zooxanthellae. The $\delta^{15}N$ values had a tendency to be similar to, or even lighter than, those of the zooxanthellae.

Fig. 4 shows the mean differences in $\delta^{15}N$ ($\Delta\delta^{15}N$) between coral tissue and zooxanthellae at each locality. During the dry season, the mean differences in $\delta^{15}N$ were always positive, while during the rainy season the differences were negative. The $\Delta\delta^{15}N$ is statistically different between the dry season and the rainy season at the 95% confidence interval (ANOVA, $p < 0.000$). This result suggests that during the rainy season the corals utilize food sources other than the zooxanthellae. Since November is the beginning of the rainy season and algal blooms, the corals are likely to be using POM as their main source of organic nutrient compounds

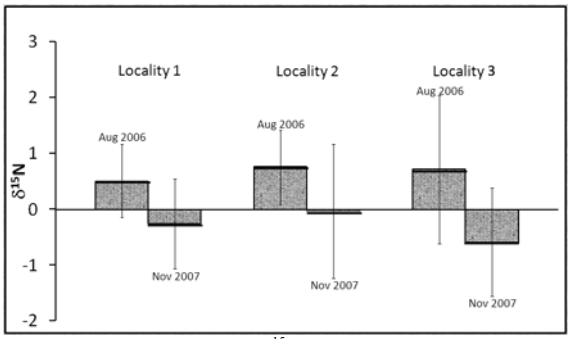

Figure 4. Average values of $\delta^{15}N$ differ seasonally between coral tissue and zooxanthellae at each of the three localities. During the dry season, the $\delta^{15}N$ values of the coral were heavier than those of the zooxanthellae, as indicated by the positive values, while during the rainy season, coral $\delta^{15}N$ values were lighter than zooxanthellae values.

Another possibility is that corals mainly consume zooplankton during the rainy season. However, during the dry season, the $\delta^{15}N$ value of the zooplankton was 7.1±1.2‰, while during the rainy season it was 5.1±0.1‰. These results show that the $\delta^{15}N$ values of marine zooplankton during both seasons were heavier than coral values. The heavier $\delta^{15}N$ values of the zooplankton imply that these branching coral reefs do not depend on zooplankton as their main food source.

Conclusion

This study documents the $\delta^{13}C$ and $\delta^{15}N$ values from three branching coral species; *Stylophora sp., Seriotopora sp.,* and *Porites sp.,* collected in two different seasons and at different turbidity levels. Different trends for the $\delta^{15}N$ values of coral tissue and the zooxanthellae were detected for each season. The majority of the coral tissue samples collected during the dry season had $\delta^{15}N$ values lighter than the zooxanthellae, but during the rainy season the opposite trend was observed.

Sedimentation rates only slightly affected the $\delta^{15}N$ values at the three localities. In spite of the fact that the coral polyps depend on zooxanthellae as a source of nutrients, our results suggest that the polyps also feed on POM from the surrounding waters which is probably produced during algal blooms (Muscatine and Kaplan, 1994). Moreover, coral tissues have previously been reported to have adapted their feeding habits from autotrophic to heterotrophic (Anthony and Fabricius, 2000). They are able to use POM as a food source.

Through direct observation and based on the results Suhendra (2006), we recognized that there is a difference in turbidity levels between Locality 1 and Locality 3. The sediment fraction at Locality 1 was dominated by silt which may come from the Berau River. The sedimentation rate for Locality 1 was also higher than the other localities (Suhendra 2006). However, this study did not detect isotopic differences between coral tissue and zooxanthellae in turbid water versus clear water.

Reef-building coral *Goniastrea aspera* harbor a novel filamentous cyanobacterium in their skeleton

S.S. Yamazaki [1], T. Nakamura [1,2], Y.S. Yuen [1], H. Yamasaki[1]

Abstract. Reef-building corals harbor diverse communities of cyanobacteria, algae, bacteria and fungi within their skeleton. In spite of their potential significance, the interaction between these microbes and host corals is still obscure. Here we report a novel cyanobacterium within the skeleton of *Goniastrea aspera*, a massive reef-building coral that is predominantly found in shallow reef habitats. Characteristics of this cyanobacterium are: (1) non-branching filaments having a 1 μm diameter, (2) lack of heterocysts, (3) hormogonia formation, and (4) Chl *a* as the sole chlorophyll pigment. Consistent with these phenotypic traits, 16S rDNA sequence analysis showed a close association with this cyanobacterium to *Halomicronema,* a recently identified genus that includes species found in benthic microbial mats of hypersaline ponds. A possible interaction between *Halomicronema* sp. and the host coral is discussed in terms of stress tolerance.

Key words: Cyanobacteria, coral skeleton, endolithic algae, *Goniastrea aspera*, *Halomicronema* sp.

Introduction

The obligate symbiotic relationship between reef-building corals and dinoflagellates (zooxanthellae) is well recognized (D'Elia and Wiebe 1990). In addition to this well-established relationship, coral tissue and coral skeleton are also known to harbor diverse microbial consortia (Rohwer et al. 2002; Le Campion-Alsumard et al. 1995a). Until recently, however, these coral-microbial interactions remain obscure (Le Campion-Alsumard et al. 1995b)

The presence of endolithic microorganisms in skeleton of corals was first discovered in 1902 by Durden (Durden 1902). Visible green bands usually observed in the skeletons of massive corals comprised of cyanobacteria, fungi, bacteria, red and green algae (Le Campion-Alsumard et al 1995a; Schlichter et al. 1997). Among endolithic microbes, *Ostreobium* spp. are frequently found in coral skeletons (Lukas 1974).

The function of bioerosion that contributes to the geochemical and sedimentological importance in the reef was documented (Kobluk and Risk 1977). Also, endolithic microorganisms have been considered to be one of the major primary producers in coral reef environments (Tribollet et al. 2006). Recent findings have shown that endolithic algae transfer photoassimilates to coral host (Fine and Loya 2002; Lesser et al. 2007). This serves an alternative nutrient source especially during bleaching events. More recently, endolithic algae was reported to possess a photoprotective role in the coral-algal photosynthesis during high-light stress (Yamazaki et al. 2008).

Coral skeleton covered by living coral tissue is a harsh environment for the growth of many organisms (Shashar and Stambler 1992). This environment partly shares a similarity with that for microbial mats that harbor diverse microbial communities (Fourçans et al. 2006). In the intertidal reefs in Okinawa, Japan, massive coral *Goniastrea aspera* is constantly being exposed to a strong sunlight and high salinity during low tides. In this study, we report an endolithic community found within the skeleton of *G. aspera* .

Material and Methods

Colony of massive coral *Goniastrea aspera* (approximately 5-6 cm in diameter) was collected in June 2004 from a shallow intertidal pool of Bisezaki, Okinawa Japan. Coral tissue was removed using a WaterPik (Johhannes and Wiebe 1970) and coral skeleton was crushed to small fragments (approximately 1 cm in diameter) with a chisel. Skeletal fragments were then trimmed off with anatomical scissors to small pieces < 2 mm in length). The crushed skeletal pieces of *G. aspera* containing green bands were investigated utilizing culture method, microscopic observations, pigments analysis and molecular techniques.

Small pieces of coral skeleton were incubated in a liquid A medium (Mitsui and Cao 1988). Nitrogenous compounds were omitted from this medium to prevent the growth of undesirable microorganisms. The culture medium was modified to include sterile coral tissue extraction. Repeated subcultures of

colonies were carried out on agar plates to obtain a pure culture of cyanobacterium. All cultures were incubated at 28°C under a 12h dark : 12h light (30 µmol photons m^{-2} s^{-1}) photoperiod. The cultured cyanobacterium was used for pigment analysis and DNA analysis.

For microscopic observation, pieces of trimmed coral skeleton were ground in sterilized seawater using mortar and pestle. The samples were observed under a fluorescence microscope.

Pigments extracted from the green band and the cultured cyanobacterium were analyzed by thin layer chromatography analysis (TLC). Coral tissue was removed with a WaterPik as the described above. The tussue-removed skeletons were crushed in 90% acetone at 4°C, and were centrifuged at 10,000 x *g* for 2 min and the supernatant was used for TLC analysis. The cultured cyanobacterium was collected by centrifugation (15,000 x *g*, 3 min). The supernatant was then discarded and the cyanobacterial pellet was homogenized in 90% acetone at 4°C, and it was centrifuged at 15,000 x *g* for 3 min and the supernatant was used for TLC analysis. All procedures were carried out under a dim light. TLC analysis was carried out on a reverse phase C_{18} plate (MERCK) with 100% MeOH as the developer. The spots of chlorophyll pigments were visualized under a blacklight (UVP UVL-56).

Total genomic DNA of the cultured cyanobacterium was extracted using the UltraClean Soil DNA Kit (MoBio, Solana Beach, CA). PCR was performed using the primers of fD1 (5'-AGAGGATGATCAGCCACACTG-3') and rP2, which were designed for eubacterial 16S rDNA (Weisburg et al. 1991). The reaction mixture (50 µl) contained 0.15 mM deoxynucleotides (Takara, Tokyo, Japan), 0.2 µM forward primer, 0.2 µM reverse primer, 2µl of the PCR template and 0.05 U of recombinant *Taq* DNA polymerase (Takara) per µl in PCR buffer (Takara). The temperature program for 30 cycles of PCR was 94°C for 30 s, 55°C for 1 min, 72°C for 2 min, and 72°C for 5 min as the final extension after the last cycle. The amplified DNA fragment were purified by gel percolation. The sequence was determined in opposite orientations using a Big Dye Terminator v3.1 Cycle Sequencing Kit (Applied Biosystems, Foster City, CA) with a DNA Sequencer (ABI 3100 Avant; Applied Biosystems). The obtained nucleotide sequence has been deposited in DNA Data Bank of Japan (DDBJ) with an accession number AB257773. Related sequences were aligned with CLUSTAL X 1.83 software for multiple sequence alignment, and bases of ambiguous alignment were corrected or removed manually. Tree topology was constructed with the neighbor joining method with MEGA 3.0 software (Kumar et al. 2004).

Results

Figure 1A shows the localization of green bands observed in the transverse section of *G. aspera*. It exhibits two distinct layers of green band within the skeleton. Green bands were observed just beneath and in deep of the skeleton that were separated by a light green or whitish zone. The green bands were primarily composed of photosynthetic organisms having non-branching, narrow filament approximately 1 µm in diameter as shown in Fig 1B and C.

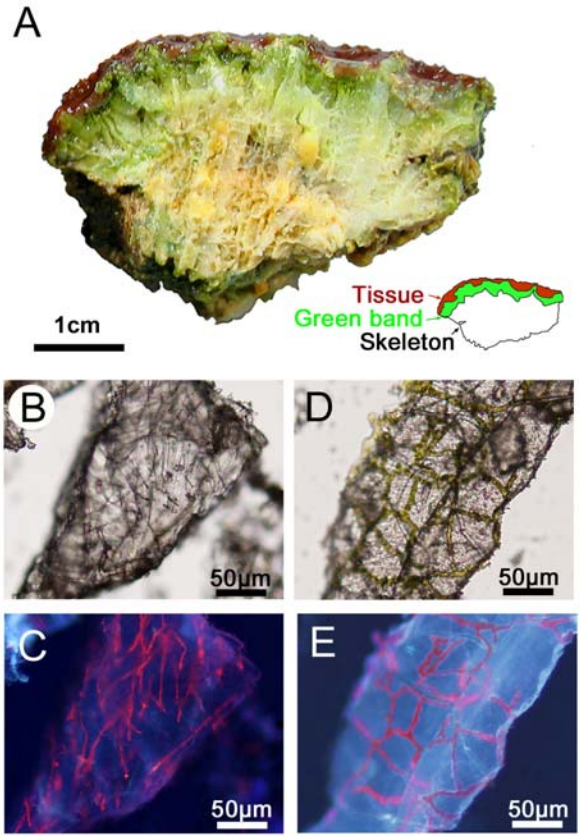

Figure 1: Layer of green band observed within the skeleton of *Goniastrea aspera*. (A) Dissected transverse section of *G. aspera* skeleton, (B and C) Photosynthetic organism found in skeletal fragments, (D and E) *Ostreobium* sp. (C) and (E) are epifluorescence images of (B) and (D), respectively.

Ostreobium sp. was observed on the fragments of the coral skeletons. The green alga showed repeatedly branching, non-septating 3 µm diameter filaments having knobby surface irregularities (Fig 1D and E). In addition to *Ostreobium* sp., coccoid photosynthetic organisms with less than 1 µm in diameter were also observed in the suspension of the green band and on the surface of skeletal fragments. These could be

attributed to the deposits during the process of tissue removal (data not shown).

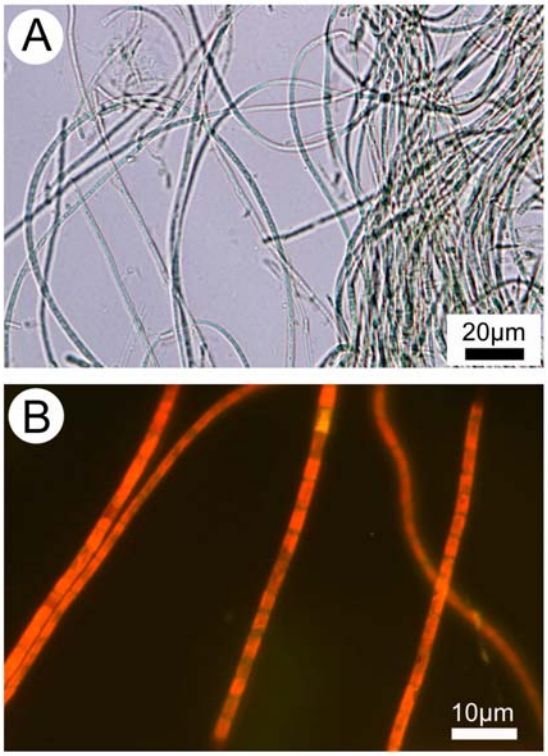

Figure 2: Morphology of the cultured filamentous cyanobacterium isolated from the green band in *G. aspera* skeleton. (A) Light micrograph of the filamentous cyanobacterium (B) Epifluorescence image of the filamentous cyanobacterium.

A cyanobacterium was successfully isolated and cultured with the modified A medium. This cultured cyanobacterium was non-branching, non-heterocyst forming, had narrow filaments around 1 μm in diameter and formed motile hormogonia (Fig 2). All these characteristics can be found in cyanobacteria belonging to the order Oscillatolariales.

Analysis of chlorophyll pigments using TLC revealed that both green band from coral skeleton and the isolated cyanobactrium contained chlorophyll *a* (Fig 3). However, chlorophyll *b* was only found in the extract obtained from the green band in the coral skeleton (Fig 3, lane A). Similar results were obtained with HPLC analysis (data not shown).

A phylogenetic tree constructed by the neighbor joining method is presented in Fig 4. A BLAST homology search of the determined sequence showed the closest identity (94%) to a 16S rDNA region of *Halomicronema excentricum*.

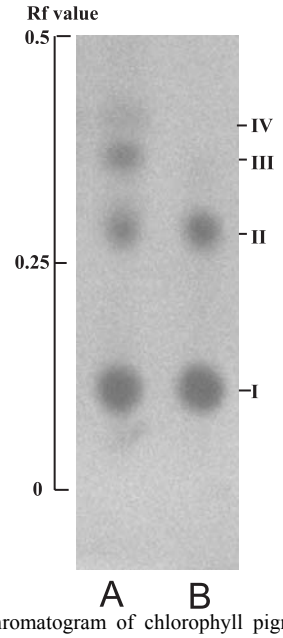

Figure 3: TLC chromatogram of chlorophyll pigments. Lane A, pigments extracted from the green band found in *G. aspera* skeleton. Lane B, pigments extracted from the isolated filamentous cyanobacterium. (I) Pheophytin *a* (II) Chlorophyll *a* (III) Pheophorbide *a* (IV) Chlorophyll *b*.

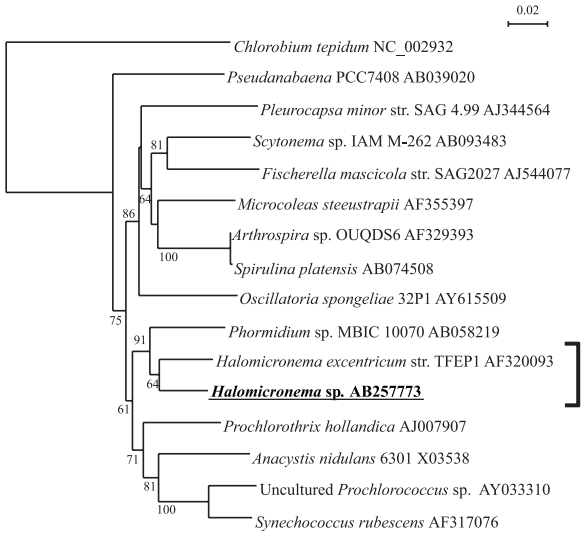

Figure 4: A phylogenetic tree constructed by the neighbor-joining method on the basis of 1029 bases 16S rDNA partial sequence. The sequence of *Chlorobium tepidum* was used as an outgroup. The scale bar represents a 0.05 substitution per nucleotide position. Numbers indicate the percentage of bootstrap support out of 1000 resampling data from the neighbor-joining method.

Discussion

To the best of our knowledge, this is the first report of a *Halomicronema* sp. inhabiting in the skeleton of a live coral. Species of the genus *Halomicronema* are one of the dominant cyanobacateria found in hypersaline microbial mat. They are characterized moderately halophilic and thermophilic (Abed et al. 2002; Fourçans et al. 2006). The present study

suggests that the internal environments of coral skeletons could be similar to the habitats for hypersaline microbial mats.

Shallow intertidal pools in coral reefs are harsh environments that accompany daily and seasonal changes in salinity and water temperature with large extents. The massive coral *G. aspera* can be dominantly found in such harsh habitats. It is interesting to note that even after the mass bleaching event in 1998, many *G. aspera* survived and increased in abundance around Okinawa Island (Loya et al. 2001). It appears that *G. aspera* is relatively stress tolerant.

Although further studies are needed to clarify the biological functions of the endolithtic microbes in *G. aspera*, we consider it plausible that the colonization brings a positive effect on the coral host. In fact, under high-light stress conditions, the *Acropora digitifera* colonies infected by endolithic microbes exhibited a photosynthetic activity higher than that of uninfected ones, a result suggesting a positive contribution of the microbes to the host physiology (Yamazaki et al. 2008). Endolithic microbes within coral skeleton may act as "secondary or facultative symbionts" (Yamazaki et al. 2008).

Endolithic algae found in coral skeletons have been reported to facilitate the host recovery from a bleached condition (Fine et al. 2002). *Halomicronema* was reported to have halophilic and thermophilic characteristics. High temperature and high salinity conditions in a shallow intertidal pool may allow the dominance of *Halomicronema* sp. within *G. aspera* skeleton. The presence of such stress-resistant microbes would contribute to the overall stress tolerance of *G. aspera*.

From bacterial bleaching to the hologenome theory of evolution

E. Rosenberg[1] and I. Zilber-Rosenberg[2]

1) Dept. Mol. Microbio.l and Biotechnol., Tel Aviv University, Ramat Aviv, Israel 69978
2) Open University of Israel, Raanana, Israel 43107

Abstract. Extensive bleaching of the coral *Oculina patagonica* in the eastern Mediterranean Sea occurs every summer when the seawater temperature exceeds 25°C. The infection by *Vibrio shiloi* and subsequent bleaching occurred only above 25°C because several of the bacterial virulence factors, superoxide dismutase, adhesion and toxin P, are only expressed above 25°C. Starting in 2002, the corals developed resistance to *V. shiloi*. Attempts to explain the resistance led to the Coral Probiotic Hypothesis, which posits that corals can adapt to their environment, including resistance to pathogens, by changing their symbiotic bacteria. The hologenome theory considers the holobiont a unit of natural selection. The hologenome is defined as the sum of the genetic information of the host and its microbiota. The theory is based on four well documented generalizations: (1) All animals and plants establish symbiotic relationships with microorganisms. (2) Symbiotic microorganisms are transmitted between generations. (3) The association between host and symbiont affects the fitness of the holobiont. (4) Under environmental stress, the symbiotic microbial community can change rapidly. These points taken together suggest that the genetic wealth of diverse microbial symbionts can play an important role both in adaptation and in evolution of higher organisms.

Keywords: Coral bleaching; *Vibrio*; holobiont, hologenome, evolution

Introduction

Extensive bleaching of the coral *Oculina patagonica* in the eastern Mediterranean Sea occurs every summer. Kushmaro et al. (1996, 1997) reported that the bleaching of *O. patagonica* was the result of an infection by *Vibrio shiloi*. The demonstration that *V. shiloi* was the causative agent of the disease was established by rigorously satisfying all of Koch's postulates, including the fact that bleached corals in the sea contained the bacterium (Kushmaro et al. 1996, 1997) whereas it was absent from healthy corals. Furthermore, Kushmaro et al. (1998) showed that the infection and subsequent bleaching only occurred at temperatures above 25°C. Thus, for bleaching to occur, both elevated temperature and the causative agent must be present.

The specific steps in the infection of *O. patagonica* by *V. shiloi* have been studied extensively (Rosenberg and Falkovitz 2004). The bacteria are chemotactic to the coral mucus, adhere to a β-galactoside-containing receptor on the coral surface, penetrate into the epidermal layer and multiply intracellularly, reaching 10^8 -10^9 cells per cm^3. The intracellular *V. shiloi* produces an extracellular peptide toxin (PYPVYPPPVVP) that inhibits algal photosynthesis. Another important factor for the virulence of *V. shiloi* is the expression of superoxide dismutase (SOD). Adhesion, production of the toxin and expression of SOD are all temperature-dependent reactions, occurring at summer (25-30°C) but not winter (16-20°C) temperatures. Thus, *V. shiloi* can not infect, multiply or survive in the coral during the winter. Sussman et al. (2003) demonstrated that the marine fireworm *Hermodice carunculata* is a winter reservoir and spring-summer vector for *V. shiloi*.

Development of resistance of O. patagonica to V. shiloi

We have been studying the *V. shiloi/O. patagonica* model system of coral bleaching in the sea and in the laboratory for over ten years. Sometime between 2002 and 2004 we found that the corals became resistant to the pathogen. The evidence for the development of resistance is based on the following (Reshef et al. 2006):

1. From 1995-2002, the pathogen *V. shiloi* was readily isolated from 46/50 bleached and bleaching corals collected from the wild; from 2004 to the present, we have been unable to isolate *V. shiloi* from bleached or bleaching corals.
2. From 1995-2002, all laboratory strains of *V. shiloi* caused bleaching in controlled aquaria experiments; from 2004 to the present, none of the same strains bleach *O. patagonica* in the laboratory.
3. From 1995-2002, *V. shiloi* adhered to the corals, penetrated into the ectoderm and multiplied intracellularly to 10^8-10^9 cells per cm^3; now, *V. shiloi* adheres, penetrates the ectoderm and is rapidly killed.

Before the corals became resistant, the isolation and infection was so reproducible that for several years we used the system to demonstrate Koch's postulates in the teaching laboratory. Not only can we now **not**

isolate *V. shiloi* from bleached corals, but molecular techniques failed to recover the 16S rRNA gene from ca. 1000 clones that were sequenced (Koren and Rosenberg 2006). Recently, Ainsworth et al. (2008) confirmed that *V. shiloi* is not currently present in bleached *O. patagonica*, using FISH technology.

The coral probiotic hypothesis

The studies summarized above indicate that corals can indeed adapt rapidly to changing environmental conditions by altering their population of symbiotic bacteria. These studies led us to propose the Coral Probiotic Hypothesis (Reshef et al. 2006). This hypothesis posits that a dynamic relationship exists between symbiotic microorganisms and environmental conditions which brings about the selection of the most advantageous coral holobiont. Changing their microbial partners would allow the corals to adapt to changing environmental conditions more rapidly (days to weeks) than via mutation and selection (many years). An important outcome of the Probiotic Hypothesis would be development of resistance of the coral holobiont to diseases. The following evidence supports this hypothesis: (i) Corals contain a large and diverse bacterial population associated with their mucus and tissues. (ii) The coral-associated bacterial population undergoes a rapid change when environmental conditions are altered. (iii) Although lacking an adaptive immune system (no antibodies), corals can develop resistance to pathogens. One potentially contributing factor is the production of antibacterials by coral mucus bacteria (Ritchie 2006). The Coral Probiotic Hypothesis may help explain the evolutionary success of corals and moderate the predictions of their demise.

The hologenome theory of evolution: role of microorganisms in the evolution of animals and plants

The hologenome theory of evolution (Rosenberg et al. 2007; Zilber-Rosenberg and Rosenberg 2008) is a generalization of the coral probiotic hypothesis. More than a hundred years of biological research has demonstrated the importance of microorganisms in the health and disease of higher organisms. As a result of the recent development of culture-free molecular techniques, it is now accepted that in many cases the number of symbiotic microorganisms and their combined genetic information far exceed that of their hosts. The hologenome is defined as the sum of the genetic information of the host and its microbiota. In the hologenome theory of evolution, we suggest that the holobiont (Margulis 1993; Rohwer et al. 2002) (the host and its symbiotic microbiota) with its hologenome, should be considered a unit of selection in evolution, and that relatively rapid variation in the diverse microbial symbionts can have an important role in the adaptation and evolution of the holobiont. In essence, the hologenome theory of evolution focuses on the holobiont as a single dynamic entity in which a vast amount of the genetic information and variability is contributed by the microorganisms. Evolution of the holobiont can occur by changes in the host genome and/or in any of the associated microbial genomes, and relies on cooperation between the genomes within the holobiont, as much as on competition with other holobionts. A large body of empirical data provides the foundation for the hologenome theory of evolution. We choose to discuss this information within the following framework: (1) all animals and plants establish symbiotic relationships with diverse microorganisms. (2) Symbiotic microorganisms can be transmitted between generations with fidelity. (3) The association between host organism and its microbial community affects the fitness of the holobiont within its environment. (4) Genetic variation in holobionts can be enhanced by incorporating different symbiont populations and can change under environmental demand more rapidly and by more processes than the genetic information encoded by the host organism alone.

All animals and plants establish symbiotic relationships with microorganisms

Eukaryotes presumably arose from prokaryotes (Margulis 1993) and have remained in close relationship with them ever since. It is therefore not surprising that the surfaces of animals and plants contain a great abundance and variety of microorganisms. In addition, some microorganisms are able to grow inside animal or plant cells, i.e., endosymbionts. Because the vast majority of microorganisms that have been observed on or in animal and plant tissues cannot be cultured, current research on the diversity of microorganisms associated with a particular species relies primarily on culture-free DNA-based technology (Hugenholtz et al., 1998). Although censuses of microorganisms associated with different animal and plant species are only in an early stage, certain interesting generalizations have emerged: (1) The diversity of microbial species associated with a particular animal or plant species is high. (2) The host associated microbial community is very different from the community in the surrounding environment (Frias-Lopez et al. 2002; Rohwer et al. 2002; Sharp et al. 2007). (3) In some cases it has been shown that similar, but not identical, microbial populations are found on the same species that are geographically separated, while different populations are found on different species at the same location (Rohwer et al. 2002; Lambais et al. 2006; Fraune and Bosch 2007). (4) Different microbial communities often dominate different tissues of the same organism (Tannock 1995; Koren and Rosenberg 2006; Dethlefsen et al.

2007). (5) In several cases where a large diversity of associated bacterial species exists, certain bacterial groups dominate.

Transmission of symbionts between holobiont generations

The hologenome theory of evolution relies on ensuring the continuity of partnerships between holobiont generations. Accordingly, both host and symbiont genomes must be transmitted with accuracy from one generation to the next. The precise modes of vertical transmission of host genomes are well understood and need not be discussed here. However, in recent years, it has become clear that microbial symbionts can also be transmitted from parent to offspring hosts by a variety of methods. McFall-Ngai (2002), in an insightful review on the influence of bacteria on animal development, divided the modes for maintaining symbionts faithfully between generations into two categories, transovarian and environmental transmissions, while correctly acknowledging that there are numerous intermediate cases. We would like to take this approach one step further by suggesting that the numerous intermediate cases, in fact, best describe the large variety in modes of transmission, which are known at present to reconstitute plant and animal holobionts. It is this continuum of modes of transmission from direct to indirect that makes it impractical to place them in any specific categories.

Direct transmission from parent to offspring occurs with some symbionts where the microorganisms are in or on the reproductive cells. For example, in the aphid–Buchnera symbiosis, bacteria are intracellularly situated in bacteriocytes and are transferred to and transmitted via the eggs (Baumann et al., 1995). Direct contact is another slightly less direct mode of transmission demonstrated in mammals in which many of the symbionts are derived during passage through the birth canal or subsequently by close physical contact with parent or family and community members.

Another slightly less direct mode of transmission is used in the termite hindgut–microbiota symbiosis where feces of adult termites (containing abundant microorganisms) are fed to newly hatched juveniles by workers in the colony (Abe et al. 2000).

Cooperation between the host and the microbiota contributes to the fitness of the holobiont

Natural selection is the central concept of Darwinian theory – the fittest survive and spread their advantageous traits through populations, but 'fittest' is not an absolute property because it varies with environmental influences. Considering the holobiont as a unit of selection in evolution, we argue that the cooperation between the normal microbiota and the host generally leads to improved fitness. In addition, the genetic diversity of the microbiota can extend the range of environments in which the holobiont can compete successfully.

In several well-studied cases, neither the host nor the primary symbiont can survive without the other (absolute mutualism). For example, in the aphid–Buchnera symbiosis, the primary endosymbiotic bacterium has lost many genes required for independent growth during evolution, whereas the aphid partner depends on essential amino acids lacking in its diet that are synthesized and furnished by the symbiont (Baumann et al., 1995). While the aphid–Buchnera primary endosymbiosis is an example of absolute dependency, most of the symbiosis systems are not based on life or death interactions, but rather the microbial partners contribute in different degrees to the holobiont's well-being. One such example, also found in the aphids, is the secondary endosymbioses with bacteria belonging to a number of distinct lineages within the Gamma- and Alphaproteobacteria. These microorganisms are intracellular endosymbionts, which are not essential for growth and reproduction, but that contribute to the fitness of the holobiont (Russell et al. 2003). Regardless of the extent of dependency, a large body of data has been accumulated in recent years demonstrating that both endosymbionts and exosymbionts play numerous roles in metabolism, regulation, disease resistance and in sex and fertility determination (which may lead to species determination) of their hosts.

In the human gut–microbiota relationship a substantial amount of recent information has been gathered regarding many facets of this interaction (Xu and Gordon 2003; O'Hara and Shanahan 2006; Xu et al. 2007). The diverse interactions reported between the human gut and its microbiota include not only the cooperation in food breakdown [e.g. fiber into short-chain fatty acids (Hooper et al. 2002)] and biotransformation of certain molecules [e.g. bile acids (Hylemon and Harder, 1998)] but also participation in the development and normal function of the innate and adaptive immune systems in the gut (Hooper and Gordon 2001; O'Hara and Shanahan 2006), participation in the structural buildup of blood vessels [angiogenesis (Stappenbeck et al. 2002)] and participation in the regulation of fat accumulation (Bäckhed et al. 2004).

Genetic variation in holobionts

Variation is the raw material for evolution. According to the hologenome theory of evolution, genetic variation can arise from changes in either the host or the symbiotic microbiota genomes. Variation in host genomes occurs during sexual reproduction, chromosome rearrangements and ultimately by mutation. These same processes occur in microorganisms with the noteworthy difference that in haploid bacteria recombination occurs, within the same species, by conjugation, transduction and DNA transformation. In addition to recombination and

mutation, changes in the genome of the microbiota of holobionts can occur by three other processes: microbial amplification, acquisition of novel strains and horizontal gene transfer between different species. These three processes can occur rapidly under environmental demand and may be important elements in the evolution of animals and plants (Dinsdale et al. 2008).

Microbial amplification is the most rapid and easy to understand mode of variation in holobionts. It involves changes in the relative numbers of the diverse types of associated microorganisms that can occur as a result of changing temperatures (for plants and invertebrates), nutrient availability, exposure to antibiotics or other environmental factors. The holobiont is a dynamic entity with certain microorganisms multiplying and others decreasing in number as a function of local conditions. An increase in the number of a particular microbe is equivalent to gene amplification. Considering the large amount of genetic information encoded in the diverse microbial population of holobionts, microbial amplification is a powerful mechanism for adapting to changing conditions.

Another mechanism for introducing variation into holobionts is acquiring new symbionts from the environment. Animals and plants come in contact with billions of microorganisms during their lifetime. It is reasonable to assume that occasionally, as a random event, one of these microorganisms will find a niche and become established in the host. Under the appropriate conditions, the novel symbiont may become more abundant and affect the phenotype of the holobiont. Unlike microbial amplification, acquiring new symbionts can introduce entirely new genes into the holobiont.

Based solely on the host genome, animals and plants would evolve slowly because of (1) their relatively long generation times, (2) the fact that only changes in the DNA of the germ line are transmitted to the next generation and (3) often a whole set of new genes is required to introduce a beneficial phenotypic change. If the environment changes relatively rapidly, the host genome alone may not evolve quickly enough and the organism may lose competitiveness and become extinct. We argue that rapid changes in the symbiotic microbiota could allow the holobiont to adapt and survive under changing environmental conditions, thus providing the time necessary for the host genome to evolve. In some cases, the required new function remains within the symbiotic microbiota. For example, the animals that first evolved to feed on cellulose never developed the genes to degrade cellulose, but rather adapted to provide better conditions for microbial degradation of the polymer.

Discussion

The distinguishing feature of the hologenome theory is that it considers all of the diverse microbiota associated with the animal or the plant as part of the evolving holobiont and that changing the microbial community by amplification, novel acquisition from the environment and horizontal gene transfer provide additional mechanisms for rapid evolution. The consequences of considering all of the diverse symbiotic microbiota of the holobiont (endo and exocellular) are far reaching. Most importantly, they can increase the genetic information of the holobiont severalfold. Microbially directed processes can regulate and extend the metabolic capability of holobionts, including degradative and biosynthetic reactions in addition to regulatory mechanisms.

In terms of modern Darwinian theory, the unit of selection in evolution must contain two properties (Lloyd 1994): the replicator or genome that is subject to variation, and the interactor or phenotype, that interacts with the environment in a way that creates differential reproduction. The data reviewed in this article clearly demonstrate that both properties are expressed by the holobiont. The usefulness of considering the holobiont, with its hologenome, as a unit of selection is that it makes adaptability to changing environments in a relatively short time frame more comprehensible and amenable to experimental tests.

Interestingly, the hologenome theory incorporates aspects of both Darwinism and Lamarckism. Individual organisms evolve by selection of random variants, whereas the holobiont can evolve by adaptive processes. Consider, for example, marine invertebrates living in an ocean of increasing temperatures. The hologenome will change as a result of the shift-up in temperature by amplification of those microbiota symbionts that grow better at the higher temperature and possibly by gaining more thermophylic microorganisms from the environment. The holobiont will not only be better adapted to its environment, but it will also have an increased probability of passing on the acquired genetic traits to the next generation. Thus, when considering a holobiont, rather than the individual organisms that comprise it, it is possible to have an inheritance of acquired characteristics. How important this is in long-term evolution is debatable. However, in the short term, inheritance of acquired characteristics by holobionts may help them survive, multiply and buy the time necessary for the host genome to evolve.

Dimethylsulfoniopropionate is linked to coral spawning, fish abundance and squid aggregations over a coral reef

J.L. DeBose[1,2], G.A. Nevitt[1]

1) Department of Neurobiology, Physiology & Behavior, University of California – Davis, One Shields Avenue, Davis, CA 95616, USA

Coral reefs are frequently used as transient aggregation sites for foraging and spawning by marine fishes. These fishes may use predictable changes in chemical cues associated with reefs as signals to coordinate their aggregations. Dimethyl sulfide (DMS) and its precursor, dimethylsulfoniopropionate (DMSP), are ubiquitous compounds associated with productive areas, preferred sites for foraging and spawning of pelagic species. It is possible that species may recruit to DMS or DMSP (DMS/P) signatures associated with these areas. Here we investigate how temporal variation in the abundance of reef fishes and squid related to changes in DMS/P during a coral spawning event. During 2003, we recorded significant increases in water column DMS/P during a coral spawning event and found that an elevation in DMS/P was paralleled by a surge in numbers of pelagic fishes, *Caranx* spp*.,* and squid, *Loligo roperi,* over the reef. The changes in pelagic fish and squid abundance were positively correlated with DMS/P, suggesting that these animals may cue to the release of specific compounds during spawning. These results, coupled with other recent studies, provide further evidence that DMS/P may be used by fishes and squid to coordinate their aggregations over reefs.

Key Words: DMSP, pelagic fish, squid, aggregation, coral spawning

Introduction

Dimethyl sulfide (DMS) has been studied intensively by atmospheric and process-oriented oceanographers for its role in global climate, marine sulfur cycles and phytoplankton physiology (e.g., Curran and Jones 2000; Kiene *et al.* 2000). Dimethylsulfoniopropionate (DMSP) is a water-soluble osmolyte produced by species of marine phototrophic algae and is the major precursor of the volatile compound, dimethyl sulfide (DMS). DMSP is converted to DMS and acrylic acid by bacterial and algal enzymatic degradation (Kiene *et al.* 2000) and this metabolic conversion is accelerated during grazing by zooplankton (Dacey and Wakeham 1986; Daly and DiTullio 1996). Since the release of DMS and DMSP can be a by-product of zooplankton feeding (Cantin *et al.* 1996), its patchy distribution in the marine environment may reflect grazing rate (Kwint and Kramer 1996; Wolfe and Steinke 1996). Further, Hill and Dacey (2006) found that dissolved DMSP is released into the water immediately after foraging by planktivorous fishes.

Coral reefs are significant production sites for DMS and DMSP (Broadbent and Jones 2004). Reefs appear to produce DMSP in part through interactions between coral and their symbiotic zooxanthellae (Hill et al. 1995; Van Alstyne et al. 2006). Zooxanthellae taken from *Acropora* coral tissues from the Great Barrier Reef produce up to 285 fmol DMSP per cultured cell and up to 3831 fmol per cell in corals (Broadbent et al. 2002). Further, Broadbent (1997) reported an increase in water column DMS and DMSP the day after a mass coral spawning and attributed it to the corals' release of mucus and eggs containing zooxanthellae.

We are only beginning to understand the roles of DMSP and DMS as signal molecules in marine and terrestrial ecosystems (see Nevitt *et al.* 1995; Zimmer-Faust *et al.* 1996; Steinke *et al.* 2006; DeBose *et al*. 2006, 2007, 2008). High DMS and DMSP concentrations over productive marine areas can be long-lasting (hours to days; Ledyard and Dacey 1996) and thus, provide predictable cues that may be used by organisms to locate habitat. For instance, frontal zones are productive areas where seabirds (Nevitt 2000), Humboldt penguins (see Culik 2001), and basking sharks (Sims and Quayle 1998) forage on dense plankton patches. Nevitt (2000) has implicated air-borne DMS as part of an 'olfactory landscape', which can be detected by pelagic Procellariiform seabirds in search of productive areas for foraging. Humboldt penguins increase their anticipatory activity in the presence of DMS, suggesting that penguins could use DMS as a foraging cue as well (Culik 2001). Similarly, Sims and Quayle (1998) suggest that basking sharks might use DMS to locate dense patches of plankton along frontal zones.

There are many other examples of pelagic fish and other organisms that aggregate over particular sites in the marine environment. Many of these known aggregation sites are highly productive areas, such as frontal zones (Sims and Quayle 1998), seamounts (reviewed by Genin 2004), and coral reefs (reviewed by Domeier and Colin 1997). Could scented compounds associated with plankton-rich frontal zones and coral reefs, including DMS and DMSP, represent an aquatic counterpart to the olfactory landscape used by foraging seabirds?

Whether marine organisms use variations in DMS/P as habitat cues has never been explicitly tested, but there is evidence that they can detect DMSP at biologically appropriate concentrations. Nakajima and coworkers (1989, 1996) have shown through electrophysiological and behavioral trials that several species of fresh- and saltwater fish respond to DMSP (see DeBose et al. 2006). Initial field studies have also suggested that fish may be able to use DMSP as an aggregation cue in their natural environments (DeBose and Nevitt 2007; DeBose et al. 2008). Predictable temporal or spatial DMS/P signatures, such as those produced during coral spawning, might thus provide an 'olfactory landscape' which pelagic animals may use to locate particular habitat (see Nevitt 2000).

Here we explore whether fish and squid aggregations are correlated to fluctuations of DMS/P in a natural coral reef system. We investigated this idea by quantifying whether DMS/P levels over an offshore coral reef change during a coral spawning event and examining whether these changes in DMS/P are associated with temporal changes in the abundance of pelagic fishes and squid over the same period.

Materials and Methods

Study site

The Flower Garden Banks (FGB) consist of two upraised salt domes in the northwestern Gulf of Mexico, approximately 200 km off the Texas and Louisiana coasts (USA). The reef crests of the East and West banks peak at 22-28 m and 21-27 m depths, respectively, and are topped by a thriving coral reef with over 50% coral cover (Rezak et al. 1985).

Total DMS and DMSP measurements

Water collection

Seawater samples were collected in Corning 50 mL plastic centrifuge tubes. Samples were taken by scuba divers, along 100 m transects at approximately 12 m depth (mid-water above the coral reef). Results of a preliminary study showed mid-water collections to represent the highest concentrations of total DMS+DMSP (DMS/P) (see DeBose 2008). Samples for total DMS/P were collected using scuba on August 4, 5, 18-21, 2003. Six samples were taken per dive and samples were collected on August 4-5 during the morning between the hours of 06:54-07:18 and 10:58-11:24 local time (Central Standard Time). On August 18-21 both day and night samples were taken for comparison between the hours of 16:30-17:18 and 21:10-21:35. The timing of night sampling was based on a historical record of coral spawning events and estimated from the previous years' spawning times (Gittings et al. 1992; Vize et al. 2005). Sample times were consistent over nights, so even though samples may not have been collected during peak spawning activity, the samples reflect day to day changes in DMS/P. Samples were collected prior to the coral spawning on the night of August 18, so these samples were classified, along with samples collected on August 4-5, as within the "Pre-Spawn" period. Water samples collected on August 19-21 were classified as within the "Spawn" period. After surfacing from each dive, we pipetted 20 mL of the seawater samples into '20 mL' vials and added 1 mL of 1 N sodium hydroxide (NaOH). Vials were then sealed with Teflon-coated, butyl rubber septa and aluminum caps, crimped, and stored upside down in the dark.

Water chemistry analysis

Whole water samples were preserved with 1 N NaOH, which cleaves DMSP (particulate and dissolved) into DMS, so that the two sources of DMS could not be differentiated in this study. All concentrations are therefore reported as DMS/P.

Total DMS+DMSP was quantified using a gas chromatograph (GC; Shimadzu GC-14A equipped with a FPD-14) at the Dauphin Island Sea Lab, Alabama, USA. Samples were analyzed January 26-28, 2004. Our results can be considered conservative estimates of total DMS/P, since some loss of DMS from samples might have occurred during storage.

Each 20 mL sample was vortexed, and 1 mL of the sample was then combined with 1 mL of 5 N NaOH in a 5 mL serum vial. Headspace gas in the vial was captured using a modified cryotrapping method adapted from Kiene and Service (1991). The oven temperature was maintained at 70°C to adequately separate sulfur compounds. Standard preparation is described elsewhere (Kiene and Service 1991).

Coral Spawning Behavior

Seven to ten days after the first full moon in August, seven species of hermatypic corals of the Flower Garden Banks undergo their annual spawning (Gittings et al. 1992). Scuba dives to observe coral spawning were made from the diving vessel M/V Spree (Gulf Diving LLC) at the West Flower Garden Bank from August 18-20 and at the East Bank on

August 21. Observations were made by two teams of scuba divers (six total divers) for approximately 500.5 min per diver, at depths ranging between 18 and 30 m. Divers monitored coral spawning behavior every night between the hours of 20:30 and 24:00 from August 18-21. Each night, divers entered the water for consecutive, overlapping time periods in order to continuously monitor the onset and completion of coral spawning within 100 m radius of the boat. Divers quantified the number and species of coral heads spawning, and the times of spawning activity for each species.

Quantification of Fish and Squid Abundance

We used Reef Environmental Education Foundation (REEF) Roving Diver Technique surveys to quantify the abundance of reef fishes (see Pattengill-Semmens and Semmens 1998). REEF surveys were conducted between 07:00 and 22:00 and individual survey times lasted approximately 42 ± 8 min (n=72). Fish abundances were scored as: 0 (Absent), 1 (Single), 2 (Few, 2-10 individuals), 3 (Many, 11-100), 4 (Abundant, >100). Abundance scores were interpreted using a Density Index score: DI = {(S*1) + (F*2) + (M*3) + (A*4)} / (number of surveys in which species was observed) (REEF 2004).

Squid counts were recorded by instantaneous point sampling throughout the dive, using a remotely operated vehicle (ROV; Phantom, operated by National Undersea Research Center/UNCW) on August 5, and by scuba on August 4, 18-21. On August 4, dive time was 46 min (from 20:50 to 21:36). ROV dive time was 152 min (from 18:15 to 20:47). During the spawning week, scuba dives were made between the hours of 20:32-00:07. The observation time by any one dive team ranged from 443-586 minutes over four nights, with the average nightly dive lasting 110-146 min.

Statistical Analyses

A mixed, nested ANOVA was used to analyze the effects of several factors on water column DMS/P: Date, Period (Pre-Spawning or Coral Spawning), Bank (East or West Flower Garden Bank), and Day/ Night collection. Date was nested within Period and Bank. The final ANOVA model was obtained by backwards elimination (eliminating factors with F < 1). Fish DI scores and squid counts failed to conform to normality and could not be transformed. Therefore, DI scores and squid numbers were analyzed using non-parametric Spearman's Rho Correlation. All statistical tests were two-tailed and performed using Statistica (StatSoft, Inc., Tulsa, OK).

Results

Total DMS+DMSP

The August 2003 spawning event (Table 1) occurred within the predicted time period (see Vize *et al.* 2005). Associated with this period of coral spawning, we observed a significant increase in water column DMS/P (Fig. 1; $F_{1,55}$ = 23.17, P = 0.0172). DMS/P levels varied among days, and showed a significant increase beginning on the first day after the initial coral spawning ($F_{3,55}$ = 3.717, P = 0.0166). DMS/P did not vary between day and night samples ($F_{1,53}$ = 0.0127, P = 0.9106). Neither did DMS/P vary between the East and West Flower Garden Bank ($F_{1,55}$ = 1.125, P = 0.3695).

Species	18-Aug-03	19-Aug-03	20-Aug-03	21-Aug-03

Table 1: Spawning times for each broadcast spawning coral species during August 2003. The number of coral heads observed spawning is in parentheses next to time frames detailing when the first and last coral head of each species released spawn.

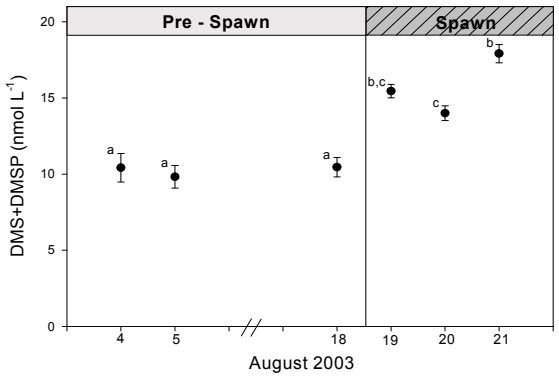

Figure 1: Total DMS+DMSP (nmol L^{-1}) in the water column increased significantly during coral spawning. Letters indicate a significant difference between days (see text).

Fish and Squid Abundance

Divers counted 133 fish species over the six days of sampling, with a maximum of 96 species on August 20-21. We found significant positive relationships between density scores for *Caranx hippos* (Fig. 2; $(r_s)_{0.05(2),6}$ = 0.8971, P = 0.0153) and *C. latus* ($(r_s)_{0.05(2),6}$ = 0.9095, P = 0.0119) and DMS/P. There was also a significant correlation between numbers of *Loligo roperi* ($(r_s)_{0.05(2),6}$ = 0.8971, P = 0.0153) and DMS/P. The abundances of *Caranx* fishes and

number of squid were not significantly related to the number of corals reported spawning (*C. hippos* $(r_s)_{0.05(2),6} = 0.6470$, $P = 0.1649$; *C. latus* $(r_s)_{0.05(2),6} = 0.7276$, $P = 0.1012$; *L. roperi* $(r_s)_{0.05(2),6} = 0.4706$, $P = 0.3462$).

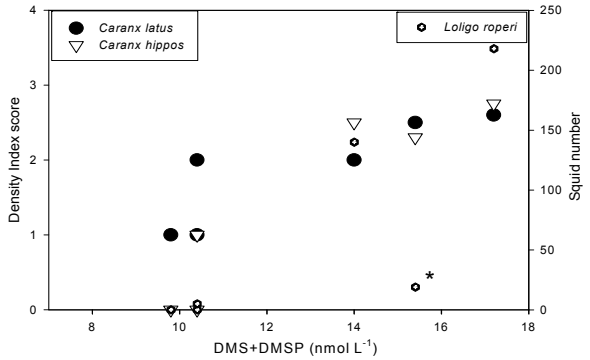

Figure 2: The density index scores for pelagic jacks (circles and triangles) and numbers of *Loligo roperi* (starred hexagons), showed positive correlations with temporal changes in DMS/P over the coral spawning period. DI scores and squid numbers are plotted against the average daily DMS/P. Asterisk denotes delay in squid numbers until after the first peak of DMS/P, which occurred on the first night of the coral spawning.

Discussion

Water column DMS/P increased significantly over the coral spawning period as compared to pre-spawning dates. The higher DMS/P concentrations were accompanied by increased abundances of pelagic fishes (*Caranx hippos* and *C. latus*) and squid (*Loligo roperi*) during the spawning period. These increases in fish and squid were associated with temporal variations in water column DMS/P rather than with the number of corals spawning.

Our data indicate that fish and squid are attracted to the coral spawning event, as evidenced by the increase in their abundances that we documented here (see also Westneat and Resing 1988; Pratchett et al. 2001). More specifically, we found the abundances of fish and squid were correlated with water column levels of DMS/P, suggesting that fish and squid may be using chemical DMS/P signatures as part of an olfactory landscape to time behaviors leading to aggregations. Based on this correlation, and similar behaviors elicited by an experimental release of DMSP (DeBose et al. 2008), we hypothesize that this attraction is mediated by temporally distinct elevations in DMS/P, or associated compounds in the water column, which serve as cues to help coordinate these behaviors. Additional chemical cues released either during spawning or by acts of predation, coupled with a changing visual landscape as fish recruit to the area, may draw in additional predatory, pelagic fishes. While in the present study we discuss this hypothesis over reef habitats, similar scenarios might also occur in upwelling areas, where primary productivity is elevated and zooplankton grazing on plankton releases substantial amounts of DMS/P and other chemicals (see Steinke et al. 2002).

Loligo roperi numbers were also significantly correlated with high levels of DMS/P. An apparent delay in the increase in squid number (shown in Figure 2) suggests squid might be using DMS/P to coordinate their activity on the reef. The schools of *Loligo roperi* recorded over the Flower Garden Banks consist of mated/mating adults and reproductively immature juveniles; the Flower Garden Banks are the only known mating grounds for this elusive squid (DeBose and Vecchione 2005).

The proximate causes for the increase in DMS/P are still undetermined. Zooxanthellae harbor high amounts of DMSP (73-117 fmol cell^{-1}: Hill *et al.* 1995; 48-285 fmol cell^{-1}: Broadbent *et al.* 2002), and the amount of zooxanthellae within coral spawn, including eggs and mucus (Muller-Parker and D'Elia 1997; Broadbent and Jones 2004) could produce a substantial release of DMSP. The highest levels of DMS and DMSP ever recorded in the marine environment were found within coral mucous ropes (DMS: 17.9 µM; DMSP: 44.9 µM) and surface waters (DMS: 219 nM; DMSPd: 630 nM) of the Great Barrier Reef (Broadbent and Jones 2004). Peak DMS/P concentrations over the FGB (2002-2003: 9.8 – 49.4 nM) did not reach the levels found by Broadbent and Jones (2004), however, the FGB are offshore reefs with notably different current regimes and tidal influences: corals do not breach the sea-surface, and mucous ropes do not appear to get trapped and aggregated within the area. Also, due to our whole-water sampling technique, the DMS/P totals could be considered averaged whereas odor plumes tend to have a filamentous structure containing high-concentration eddies (reviewed by DeBose and Nevitt 2008). This means that organisms perceiving DMS/P on finer scales would sense a higher concentration than we could capture in our samples (see Moore and Crimaldi 2004). Though the mechanism of DMSP release is still largely unknown, the evidence presented here suggests that coral spawning behavior of an off-shore reef is directly associated with increases in DMS/P over the reef.

In summary, we found an increase in water column DMS/P associated with a coral spawning event in the northwestern Gulf of Mexico. This increase was correlated with changes in pelagic fish and squid abundance. Our observations suggest that a natural increase in DMS/P might serve as a cue for foraging and/or spawning of pelagic fishes and squid. This idea provides a specific, testable hypothesis for examining how the sensory ecology of marine fishes and squid may be responsive to chemicals that originate from

the behaviors of other species (i.e., coral spawning, zooplankton foraging). Still, our explorations into this area are only beginning (see DeBose and Nevitt 2007; DeBose et al. 2008), and future work is needed to investigate DMS and DMSP as signal molecules in the marine environment.

Are tropical herbivores more tolerant of chemically rich seaweeds than are temperate herbivores? A test of seaweed-herbivore coevolution

E.E. Sotka, A. McCarty and H.B. Giddens

College of Charleston, Department of Biology, Grice Marine Laboratory, 205 Fort Johnson Road, Charleston, SC 29412

Abstract. There is a greater quantity and diversity of lipophilic secondary metabolites produced by seaweeds within tropical relative to temperate regions. Coevolutionary arms-race theory predicts that tropical herbivores should more readily tolerate consuming chemically-rich seaweeds than do temperate herbivores, however, tests of this prediction are rare. We assessed the willingness to consume freeze-dried tissue from 10 species of chemically-rich seaweeds exhibited by multiple populations of the herbivorous amphipod *Ampithoe longimana* collected from cold-temperate, warm-temperate and subtropical estuaries along the east and Gulf coasts of North America. In contrast with the coevolutionary predictions, geographic patterns of consumption of chemically-rich seaweeds were not correlated with latitude. Rather, populations in North Carolina (34ºN) consumed more tissue from the diterpene-producing seaweed genus *Dictyota* than did New England (41ºN) or Florida (27ºN) populations. Amphipod populations did not differ in their feeding responses to tissue from chemically-rich seaweeds in the genera *Amphiroa, Halimeda, Padina, Penicillus,* nor *Udotea*. Thus, Floridean *A. longimana* have not locally evolved a feeding tolerance for chemical defenses produced by tropical seaweeds, as would be predicted by an arms-race hypothesis. Rather, the geographic patterns in feeding behaviors reflect the relative importance of these seaweeds to the ecology of local populations.

Keywords. Herbivore offense, seaweed chemical defense, coevolutionary arms-race, biogeography

Introduction

Marine herbivores face profound challenges when feeding on seaweeds. Seaweeds and vascular plants generally contain low levels of nitrogen relative to herbivore tissues (Horn 1989; Choat and Clements 1998), which require herbivores to consume large quantities of plant material to maintain themselves. In addition, seaweeds have evolved structures and morphologies (e.g., crusts and calcification) that can make the algae tougher and less profitable to consume (Littler and Littler 1980; Steneck 1986; Schupp and Paul 1994). Finally, seaweeds contain an arsenal of secondary metabolites, including terpenoids, aromatics, and acetogenins, which deter herbivores (Paul 1992) and require biochemical manipulation (Targett and Arnold 2001; Sotka and Whalen 2008).

There is emerging evidence that these feeding challenges can be more profound for tropical herbivores relative to their temperate counterparts. Specifically, the concentration and diversity of lipophilic secondary metabolites within tropical seaweeds are considerably higher than those within temperate seaweeds (Hay 1991; Paul 1992; Van Alstyne et al. 2001; Pereira and de Gama 2008). In one of the few direct tests of a tropical-temperate gradient in seaweed defenses, Bolser and Hay (1996) conducted feeding assays with two urchin species (*Lytechinus variegatus* and *Arbacia punctulata*) to demonstrate that freeze-dried tissue from temperate, North Carolina seaweeds were consumed at approximately twice the rates of tissue from closely-related tropical, Bahamian seaweeds. The authors also found that the higher palatability of temperate seaweeds was mediated by either the quality or quantity of secondary metabolites within the lipophilic extract. In contrast, variation in palatability among tropical and temperate seaweeds was not mediated by water-soluble compounds or the content of protein and ash-free organic matter.

There is general agreement that this greater deterrence of tropical seaweeds and their lipophilic metabolites relative to temperate seaweeds represents a macroevolutionary response by tropical seaweeds to an intensification of herbivory rates (Hay 1991; Paul et al. 2001; Van Alstyne et al. 2001). The greater herbivory pressures in the tropics are due in part to dramatically greater diversity and abundance of herbivorous fishes in the tropics relative to temperate regions (Gaines and Lubchenco 1982; Floeter et al. 2004). However, a neglected explanation of latitudinal trends in herbivory is the notion that tropical herbivores have a greater

feeding tolerance for chemically-defended tropical seaweeds than temperate herbivores. This geographic difference in feeding tolerance would evolve if tropical herbivores have responded to the greater levels of chemical defense of their prey via a diffuse evolutionary arms-race (cf. Vermeij 1994).

One of the few tests of an arms-race hypothesis for marine plant-herbivore interactions is Cronin et al. (1997). The authors found that diterpenoid metabolites from the tropical Pacific seaweed *Dictyota acutiloba* deterred North Carolina pinfish *Lagodon rhomboides* and the purple sea urchin *Arbacia punctulata* at concentrations that did not deter fish (*Scarus shlegeli*, *Scarus sordidus*, *Naso lituratus*, and *Naso unicornis*) and an urchin *Diadema savignyi* from tropical reefs of Guam. A second example comes from the combined results of Targett et al. (1995) and Boettcher and Targett (1993), which reveal that high concentrations of polyphenolics (~10% of tissue dry weight) lowered the assimilation efficiency (AE) of the temperate fish *Xiphaster mucosus*, but did not alter the AE of two tropical fishes (*Sparisoma radians* and *S. chrysopterum*) and a tropical crab (*Mithrax sculptus*). Because the temperate fish had a far more acidic gut (pH 2-3) relative to the tropical herbivores (pH 5-9), it was suggested that hydrogen bonding among polyphenolics and proteins is enhanced within acidic guts (Targett et al. 1995).

These studies tested the arms-race hypothesis using multiple herbivore species from temperate vs. tropical regions, but another approach is to compare geographically-isolated populations within a single herbivore species. Here, we assessed the relative feeding preferences for 10 species of chemically-rich seaweeds exhibited by the herbivorous amphipod *Ampithoe longimana* collected from cold-temperate (New England; 41ºN), warm-temperate (North Carolina; 34ºN) and subtropical (Florida; 27ºN) estuaries along the east coast of North America. The small (<1cm adults) gammaridean amphipod (Arthropoda; Crustacea; Malacostraca) is a tube-dwelling brooder that lives and feeds on a variety of algae (Duffy and Hay 1991; Sotka and Hay 2002; McCarty 2008). Our arms-race prediction is that subtropical populations of *A. longimana* should more readily consume tropical, chemically-rich seaweeds relative to amphipod populations from more temperate regions.

Materials and Methods

Specimen Collection and Storage

Ampithoe longimana specimens were collected at low tide from along 1,700 kilometers across the Atlantic coast of the United States in three regions: New England (Westport, Massachusetts (41º31'N, 71º04'W), Jamestown, Rhode Island (41º29'N, 71º23'W), and Niantic, Connecticut (41º18'N, 72º10'W)); North Carolina (Harker's Island (34º43'N,76º35'W), Morehead City (34º42'N,76º40'W), and Wrightsville Beach (34º13N, 77º48'W)); and Florida ((Tampa Bay 27º45'N, 82º37'W) and Fort Pierce (27º27'N, 80º19'W)) between May of 2006 and August of 2007. We are confident that these populations are indeed *A. longimana*: Connecticut, Massachussetts and North Carolina populations readily interbreed (Sotka 2003) and published data (Sotka et al. 2003; McCarty 2008) indicate that Florida and Connecticut populations differ from each other by ~2% at a mitochondrial locus.

Amphipods were collected by hand from a variety of seaweeds and transported to Grice Marine Laboratory. Amphipods were cultured in ~30 ppt filtered seawater obtained from Grice Cove in Charleston, South Carolina at 20ºC. Water was changed every 5-7 days, and the containers were aerated constantly. Amphipods in the cultures were fed fresh *Ulva* spp., *Ectocarpus* spp., *Sargassum* spp., *Bryopsis* spp., *Gracilaria* spp., and *Hypnea* spp. collected from throughout North and South Carolina. All seaweeds were rinsed at least twice in freshwater for 30-45 seconds to remove local biota prior to being placed in the cultures. Because amphipods used in our feeding assays represent at least the 2nd generation in these 'common garden' cultures, population-level patterns in feeding behaviors likely have a genetic basis.

Seaweeds used for the feeding assays were collected in May 2005 from the upper Florida Keys (25º07'N, 80º25'W; *Halimeda* incrassata, *H. opuntia*, *H. tuna, Penicillus dumentosus, Udotea flabellum*, an unidentified *Dictyota* sp. and an unidentified *Amphiroa* sp.) and in July 2005 from near Morehead City, NC (*Dictyota cilolata*, *D. menstrualis*, *Padina gymnospora*) and in February-March 2005 from Charleston Harbor, SC (34º45'N, 79º54'W; *Ulva (syn. Enteromorpha) intestinalis*). Seaweeds were subsequently frozen at -4°C within 12 hours of collection, lyophilized, ground to a powder, and stored at -20°C for long-term storage.

Feeding Assays

To assess feeding preferences, a series of choice assays were performed using lyophilized tissue. Offering lyophilized tissue permitted experiments at different times without changing tissue quality. Lyophilization removes morphological traits but largely maintains biochemical traits that might mediate feeding choices. The process of lyophilization reduces the quantity of some secondary metabolites (Cronin et al. 1995). However, it is unlikely this potential artifact biases our conclusions because we are primarily focused on the relative differences in feeding behavior between populations exposed to the same foods.

Frozen, lyophilized algae were ground to a fine powder using a Wiley mini-mill with a 180 mm mesh sieve or ground by hand using a mortar and pestle. Food was prepared using the following recipe: 0.5 g freeze-dried seaweed mixed with 2mL H_2O added to 0.9

g of agar that was mixed and heated with 2.5 mL H_2O. The recipe was doubled, tripled or quadrupled to make sufficient food for each assay. This agar and seaweed mixture was applied to plastic screen mesh (i.e. window screen) and pressed between two sheets of wax paper for ~ less than one hour. The mesh was then cut into feeding grids measuring 5 x 6 mesh squares.

A single replicate assay consisted of one 200 mL plastic cup with ~75 mL of seawater, and a single feeding grid each of the 'Control' (*Ulva (syn. Enteromorpha) intestinalis*) and 'Treatment' food (*D. menstrualis, D. ciliolata,* etc.). Each 'Treatment' seaweed species is tropical in distribution, and is a low-preference food for several generalist fish, urchin and amphipod consumers largely because of their low nutritional value, chemical deterrents, and/or morphological defenses (Paul 1992; Bolser and Hay 1996; Pereira and de Gama 2008). *U.intestinalis* was chosen as a 'Control' because it is locally available to temperate and tropical populations of the amphipod, is readily consumed by *A. longimana*, and there are no population differences in fitness when fed *U. intestinalis* (Sotka et al. 2003).

One amphipod was placed into each replicate with the two feeding grids. Replicates were placed in covered containers in either a 20ºC or 25ºC incubator in complete darkness for the duration of the assay. Replicates were checked twice daily and stopped when five days had lapsed, or when the amphipod had consumed either 9 squares from one feeding square or a combination of 10 squares from both feeding squares, whichever was first. Replicates with fewer than 9 squares, or more than 35 squares, were excluded from analysis. Most replicates were completed within 2-3 days, but this is sufficient time to allow soluble materials to leach, including proteins, amino acids, carbohydrates and any phlorotannins. Lipophilic compounds should, however, maintain themselves on the artificial foods.

Extremes in local temperatures alter herbivore feeding behavior (Sotka and Giddens 2009). Thus, because New England populations rarely experience 25ºC, Floridean populations rarely experience 20ºC, and North Carolina populations experience both temperatures annually (Sotka and Giddens 2009), we present assay results from New England amphipods at 20ºC and North Carolina and Florida populations at 25ºC.

Paired t-tests were used to assess whether consumption rates of the two foods differed (i.e., Control vs. Treatment). To assess whether populations differed in their feeding choices, we converted the data into a proportion of treatment tissue consumed (e.g., amount of Treatment consumed divided by total amount consumed in a replicate) and analyzed this proportion using a nonparametric ANOVA using a distribution generated from a permutation method (Anderson 2001). If we had data from multiple populations within a region, then we combined all replicates for that region for analysis.

Results

During feeding choice assays, cold-temperate (New England), warm-temperate (North Carolina) and subtropical (Florida) populations consumed significantly more *Ulva* than any of the green seaweeds (*Halimeda* incrassata, *H.* opuntia, *H. tuna, Penicillus dumentosus* and *Udotea flabellum*), the red seaweed *Amphiroa* and the brown unidentified *Dictyota* species (Paired t-test $p < 0.05$ for each population / seaweed combination; Table 1). In contrast, amphipod populations tended to consume statistically equivalent amounts of *Ulva* and the brown seaweeds *Padina gymnospora, D. ciliolata* and *D. menstrualis.* However, Florida amphipods ate significantly more *Ulva* than *D. ciliolata* while North Carolina amphipods ate significantly more *D. menstrualis* than *Ulva*.

Table 1. Relative consumption of 10 chemically-rich tropical seaweeds by three populations of the herbivorous amphipod *Ampithoe longimana*. The proportion of chemically-rich seaweed consumed, sample size (n) and *p*-values are indicated for each assay. Grey boxes highlight assays where the consumption of treatment foods was significantly different (i.e., less or more) than of control foods.

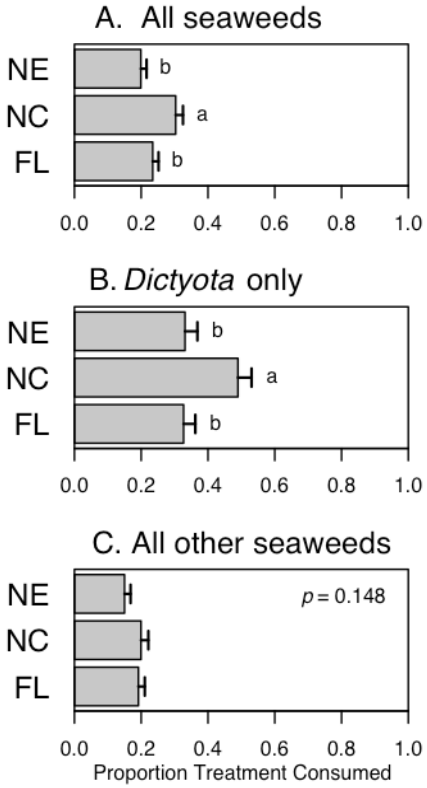

Figure 1. The average (+ S.E.) proportion of chemically-rich tropical seaweed consumed. Letters indicate groups that were significantly different.

We explicitly tested whether there are significant differences between populations in the proportion of chemically-rich tissue consumed. When all replicates are pooled, North Carolina individuals consumed significantly more of the chemically-rich tissue than did either Florida or New England populations (Figure 1A). However, as is suggested from Table 1, the regional differences in feeding preferences are driven largely by geographic variation in consumption of *Dictyota menstrualis and D. ciliolata*. Moreover, previous work has indicated that North Carolina animals use *D. menstrualis* and *D. ciliolata* as a host (Duffy and Hay 1991; Sotka and Hay 2002; Sotka et al. 2003). When we re-analyzed the feeding responses of the amphipods toward the genus *Dictyota* vs. the feeding response to the remaining seaweeds, North Carolina individuals consumed significantly more *Dictyota* tissue than did New England or Florida individuals (Figure 1B). When *Dictyota* seaweeds are removed from analysis, then there is no significant difference between the populations in the propensity to consume the other species of chemically-rich seaweeds (Figure 1C).

Discussion

Our results indicate that subtropical amphipod populations do not exhibit greater feeding preference for tropical chemically-rich seaweeds than do more temperate amphipods (Table 1; Figure 1). Rather, the warm temperate North Carolina amphipods were more likely than either the cold temperate New England or Florida populations to consume species in the genus *Dictyota*. This result does not support the notion that Florida amphipods have responded evolutionarily to chemically-rich tropical seaweeds, as would be predicted by an arms-race hypothesis.

Instead, local host use is central to understanding the evolution of these feeding behaviors (McCarty 2008). North Carolina amphipods feed readily on *Dictyota* and are readily found on *Dictyota* (Duffy and Hay 1991; McCarty 2008). This is because the *Dictyota* produces diterpene alcohols that deter larger omnivorous pinfishes that dominate the local benthos. By associating with this chemically-defended seaweed, the amphipods gain a measure of protection from their fish consumers. Neither New England nor Florida amphipods are found on *Dicytota* because *Dictyota* is not available in their local habitats (McCarty 2008). New England populations are 100's of kilometers north of the northern endpoint of *Dictyota*. In Florida estuaries, *A. longimana* are abundant where *Dictyota* appears to be rare, while on Florida coral reefs, *Dictyota* is abundant while *A. longimana* have never been found. Thus, the greater preference for *Dictyota* seen among North Carolina individuals reflects the importance of this seaweed in its local ecology.

Similarly, the lack of a regional response in feeding behavior toward the other chemically-rich seaweeds (e.g., *Amphiroa*, *Udotea*, etc.) reflects the fact that the amphipod is rarely found naturally on these seaweeds (McCarty 2008). The Florida *A. longimana* are found within estuarine seagrass beds where chemically-rich seaweeds are rare and where there are abundant seaweeds that lack chemical, morphological or mineral defenses (Hay 1984; McCarty 2008). Thus, local ecological usage of host plants clearly predicts the evolution of regional patterns in feeding behaviors.

We suggest that future tests of the latitudinal gradient in herbivore feeding tolerance utilize tropical herbivores that are regularly exposed to chemically-rich seaweeds (e.g., Cronin et al. 1997), such as urchins, crabs and fishes found on coral reefs (Hay 1984; Paul 1992). It is these reef herbivores that are most likely to be responding coevolutionarily to the chemical defenses of the local seaweeds. Our results also suggest that it may be fruitful to test whether the lower relative abundance of chemically-rich seaweeds within estuaries and seagrass beds relative to their frequencies on coral reefs (Hay 1984) might be directly reflected in the feeding tolerances of herbivores found in estuaries versus coral reefs.

Abstract. Coral reef landscapes are composed of a matrix of habitats that exhibit variation in complexity at multiple spatial scales. This variation has been shown to influence the composition of fish communities and influence the type and rate of species interactions. In this study, we quantified rates of social foraging bouts in single and mixed species groups across four habitat types (continuous reef, coral rubble-sand, reef edge, and spur and groove) at Conch Reef in the Florida Keys National Marine Sanctuary (USA). Our goal in dividing the reef landscape into particular habitat units was to ascertain if rates of social foraging vary in consistent ways in relation to habitat attributes. While there were no clear divisions in species composition that could be correlated with habitat type, rates of social foraging by mixed species groups were not equal. However, rates of social foraging bouts by single species groups were statistically equivalent across all habitat types. Fisher's diversity and species richness measures were not equal across habitat types, with lowest mean values in coral rubble habitat where rates of social foraging were highest. These results highlight the complexity of facilitative species interactions and suggest new lines of research to assess the demographic implications of such behaviors.

Key words: behavior, facilitation, group, mixed species, diversity

Introduction

Understanding processes that mediate local patterns in the diversity of organisms is central to developing assembly rules for community structure as well as for developing strategies for conservation. Much effort has been focused on understanding the roles that recruitment limitation (bottom up) versus predation (top down) play in structuring marine communities (see Doherty 1991; Hixon 1991). However, nested within the scope of these processes is the role positive species interactions play in mediating survivorship, growth and trophic interactions, each of which may influence local species diversity within a community.

Social foraging is a common type of species interaction in coral reef fish communities and can occur in single-species and mixed-species groups. Bouts of social foraging can focus on activities of a single focal animal (producer-scrounger foraging model) or focus on multiple individuals within a group (information-sharing foraging models; Giraldeau and Beauchamp 1999). In either case social foraging allows individuals enhanced access to prey resources, decreases search-time for patchily distributed prey, and provides increased protection from predators. Previous studies have focused on how social foraging enhances the fitness of individuals within a group (Wolf 1987, Overholtzer and Motta 2000) and how such interactions may mediate community composition and patterns of diversity (Auster and Lindholm 2002, Auster et al. 2005).

Coral reef landscapes are composed of a matrix of habitats which exhibit a gradient of spatial complexity at multiple spatial scales (Williams 1991; Sorokin 1995). This variation has been shown, in part, to influence the composition of fish communities (Williams 1991). It follows that such variation will also influence the scope of species interactions that may mediate local patterns of diversity.

In this study, we quantified the rates of social foraging bouts in relation to community composition across four distinct habitat types at Conch Reef in the Florida Keys National Marine Sanctuary (U.S.A.). Our goal in dividing the reef landscape into particular habitat classes was to ascertain if rates of social foraging vary in consistent ways in relation to habitat attributes. We hypothesized that rates of social foraging, if mediated by attributes of habitat, would be highest over comparatively low-relief topography where the trade-offs of predation risk and access to prey would be greatest.

Methods

Data were collected at Conch Reef (15-18.5 m depth) in the northeastern part of the Florida Keys National Marine Sanctuary from 11-18 September 2001, while using SCUBA. Conch Reef is part of the primarily Holocene reef tract along the continental margin off the south coast of Florida (Leichter et al. 2003), and is characterized by spur and groove formations. The reef landscape was divided *a priori* into four broad habitat classes (i.e., continuous reef, coral rubble-sand, reef edge, and spur and groove) in order to encompass the broadest range of spatial complexity. Reef edge and spur-and-groove habitat were similar at the scale of individual surveys in that patches contained a distinct transition zone from continuous reef to coral sand. However, these landscape features were assumed to be distinct due to differences in refuge from flow (enhanced shelter from flow within spur-and groove features) as well as differences in the location and direction of coral shelters for fishes. That is, fishes foraging in or above coral sand beyond reef edge habitat would only find shelter in the direction from where they came while fishes emerging over sand in spur-and-groove features could potentially find shelter across a sand patch in the adjacent spur (this distinction is based on unpublished observations by the authors of multiple species responding in these ways).

All data were collected during daylight hours (from 1 hr after sunrise to 1 hr before sunset). Survey patches were 5 m x 5 m (15-20 m depth). Patch delineation was estimated visually using natural landscape markers (e.g., particular coral colonies and formations). Surveys were 20 minutes in length. Observations were made while stationary in mid-water, away from patches, to minimize effects on behavior and movement of fishes but close enough to identify species. All species observed were identified to lowest the possible taxon and counted. However, no additional effort was made to census cryptic fishes (e.g., blennies, gobies) as this would disrupt foraging behaviors of the more active species.

Social foraging bouts (each "bout" defined as a single or mixed species group that exhibited coordinated search behavior) were enumerated as the number of species and the number of individuals per species involved in each bout. Actual feeding was not a pre-requisite for classification of a "bout" although one or more individuals within a group often did consume prey. Search behaviors involved non-linear swimming with individuals in each group focused on potential prey (e.g., sorting sediments, biting surfaces, attacks on vagile organisms). A bout ended when a group fully disbanded regardless of any exchange of individuals into or out of a group. The same fish may have been involved in multiple bouts within a census period, though the incidents of this were minimal. Number of surveys within each habitat varied slightly: continuous reef (n=15), coral rubble-sand (n=16), reef edge (n=11), and spur and groove (n=12).

Bray-Curtis similarity coefficients were calculated based on species abundances from surveys within and between habitats. Non-metric multidimensional scaling (MDS; 100 restarts) was used to evaluate the level of similarity in assemblage composition between habitat types (using PRIMER software; Clarke and Gorley 2001). Abundance data were log (x+1) transformed.

Data used to compare rates of social foraging (i.e., number of bouts per survey) were not normally distributed (Anderson-Darling tests for total, mixed-species and single species bouts all $p<0.05$). Kruskal-Wallis tests were used to determine if there were significant differences in rates of social foraging bouts between habitat types. Linear regression was used to determine if there were relationships between measures of local species diversity (i.e., species richness and Fisher's diversity of the fish community enumerated within each survey) and rates of social foraging.

Results

Overall 36.7% of species (i.e., 33 of 90 species from community census data) participated in either single or mixed species social foraging bouts, or both. Twenty seven species participated in mixed species groups (Table 1) while 22 species participated in single species bouts (Table 2). Six species participated only in single species bouts. Yellowhead wrasse *Halichoeres garnoti* and spotted goatfish *Pseudupeneus maculates* participated in the highest percentage of mixed species foraging bouts (33.8% and 21.6% respectively). Groups of bluehead *Thalassoma bifasciatum* composed the highest

percentage of single species bouts (19.7%) but all other species represented less than 10% each of the remaining bouts.

Results of MDS analysis (Fig. 1) indicate that there were no clear divisions in species composition that could be attributed to habitat type, although not all species occurred in all habitat types.

Comparisons of rates of social foraging based on total and mixed species bouts showed that rates of social foraging across habitats were not equal (Kruskal-Wallis tests, df = 3, H = 14.78 and 16.94; p = 0.002 and 0.001 respectively). For both comparisons, continuous reef had the lowest mean rank of all habitats and coral rubble-sand had the highest (Fig. 2 top and middle). Paired comparisons showed that coral rubble-sand had a significantly higher rate of social foraging bouts ($p<0.05$) than the other three habitat types which were not statistically different from one another. There were no significant differences in the number of single species bouts and habitat type (Kruskal-Wallis test, df = 3, H = 5.33, p = 0.149 adjusted for ties; Fig. 2 bottom).

There was no linear relationship between the total number of social foraging bouts and species richness across all surveys (ANOVA, $df_{1,52}$, F = 0.01 p = 0.91). However, when species abundances as well as richness were taken into account there was a significant linear relationship between Fisher's diversity and total bouts (ANOVA, $df_{1,52}$, F = 5.25 p = 0.03). Neither Fisher's diversity nor species richness measures were equal across habitat types (Kruskal-Wallis tests, df = 3, H = 14.15 and 10.58; p = 0.003 and 0.015 respectively) with lowest mean values in coral rubble habitat where rates of social foraging were highest (Fig. 3).

Discussion

The benefits to individuals within a foraging group generally are considered to include enhanced vigilance to predation threats and enhanced access to prey (Lukoschek and McCormick 2002). In this study we found variable rates of social foraging among habitats within a coral reef landscape despite

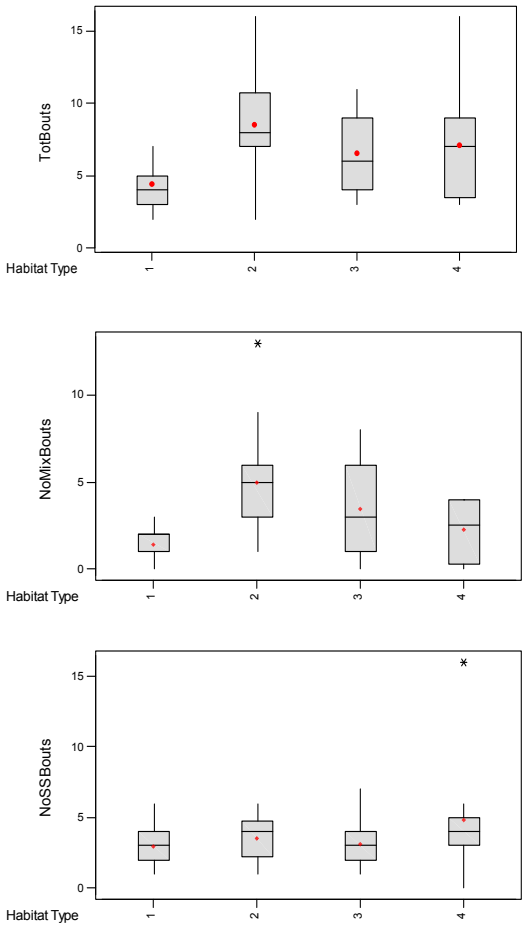

Figure 2. Boxplots of total (top), mixed species (middle) and single species (bottom) bouts per survey. Habitat types as in Figure 1. (The center-line through each box marks the median value and the solid dots mark the mean. Top and bottom of each box mark the bottom of the third and the top of first quartile of the data, respectively. The top whisker extends to the highest value in the top quartile and the bottom whisker to the lowest value in the first quartile. Stars indicate statistical outliers.)

similarity in community composition across habitats. These results suggest that structural attributes of habitat such as spatial complexity have a role in mediating behavior that balances the time and space constraints related to prey acquisition and predator avoidance.

Our *a priori* hypothesis of higher rates of social foraging in comparatively low complexity habitats was confirmed. Rates of social foraging were highest in coral rubble-sand habitats, where cover from predation was low and prey organisms are assumed to be patchy in distribution. The increased number of social foraging bouts was indicative of enhanced vigilance against threats of predation. Multiple bouts often resulted from a group breaking off and then reforming following a strike by a predator. Though predator strikes were frequent, no successful strikes were observed against individuals participating in social foraging bouts over the course of the study. Conversely, the number of social foraging bouts was lowest over continuous reef habitat where cover from predation and potential prey was ubiquitous. Here the benefits to an individual's participation in a social foraging event are assumed to be comparatively low.

It is interesting to note that fishes in this study area exhibited a lower percentage of social foraging activities than studies elsewhere. For example, 52% of species (i.e., 34 of 65 species) from community surveys on reefs off Bonaire, Netherlands Antilles, participated in mixed or single species foraging groups (Auster and Lindholm 2002). Barber and Auster (in prep) demonstrated that approximately 45% of non-cryptic reef fish species at sites in the Gulf of California and the Great Barrier Reef occurred in mixed and single species foraging groups. While all surveys were conducted within approximately the same depth range, patterns related to latitudinal gradients and relationships to the regional species pool remain to be investigated.

Observations of foraging groups elsewhere in the Caribbean, Gulf of California, Coral Sea, and Indian Ocean revealed they can be composed of

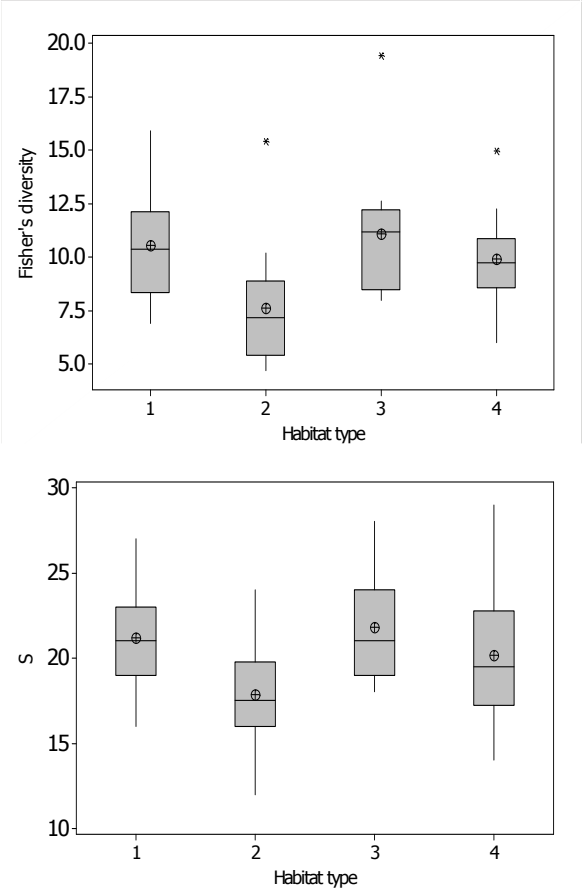

Figure 3. Boxplots of Fisher's diversity (top) and species richness (bottom) by habitat type. See legend of Figure 2 for explanation.

species representing a wide range of trophic guilds (i.e., planktivores and herbivores through piscivores; sensu Bohnsack et al. 2002) while others were limited to a particular trophic groups (Auster and Lindholm 2002, Auster 2005, 2007, Barber and Auster in prep, Auster unpublished data). Barber and Auster (in prep) showed that while all trophic guilds were represented in foraging groups at Caribbean (i.e., Bonaire) and Coral Sea (northern Great Barrier Reef) study sites, the proportions of guilds represented in foraging groups in contrast to the local community varied. While the trophic guild composition of social foraging groups at the Caribbean site reflected proportions in the local community, the guild composition of foraging groups differed significantly from the community at Coral Sea sites. Higher than expected proportions of planktivores, browsers and macro-invertivores were observed in mixed-species groups while piscivores and micro-invertivores were under-represented. However, a mechanism to explain such patterns in terms of costs and benefits remains to be discerned and will be critical for understanding the link between facilitative behaviors and population responses of component species (Auster et al. 2005, Barber and Auster in prep).

Species interactions can be explicitly linked to local patterns of diversity. For instance, a study of mixed flocks of neotropical birds suggested that such behavior may contribute to enhanced richness of rainforest avifauna (Powell, 1989). The author showed that smaller bird species in mixed species flocks foraged within a larger spatial range than when foraging singly, and suggested that each species underutilized available prey resources, thus allowing coexistence of species with high niche overlap. In the present study, local fish diversity was positively correlated with rates of group foraging, as it was at reefs off Bonaire (Auster and Lindholm 2002). In the Bahamas the combination of predator-prey and competitive interactions between reef fishes was shown to mediate patterns of local abundance of reef fishes (Carr et al. 2002). However, the role of positive (facilitative) species interactions in developing these patterns was not addressed.

Ultimately, investigating such interactions in fishes at a diversity of locations can lead to a better understanding of how behavioral interactions mediate trophic interactions and community composition. In the short term we need to better understand how quantification of such interactions can enhance our ability to evaluate the status and ecological integrity of reef fish communities.

Abstract. Coral recruitment studies provide crucial information on a reef's capacity to recover from disturbances such as storms, coral bleaching, or destructive fishing. The Sulu Sea is at the apex of a "coral triangle", yet little is known on coral recruitment or reef resilience in this area. This study aimed to determine patterns in the abundance and composition of early coral recruits in three major marine corridors of the Sulu Sea. Five hundred nineteen terracotta tiles were deployed for six months along 50-m transects in 33 sites along the Cagayan Ridge, Balabac Islands, and Verde Passage. Results show significantly higher mean recruit density in the Balabac Islands, where destructive fishing methods continue to be used, than in the Cagayan Ridge, which is a protected area. At a smaller scale, density patterns of early recruits show no direct correlations with the adjacent benthic community. High early recruit density was found in sites with derived high entrainment by currents, suggesting that physical rather than biological factors play a major role in determining early recruitment at the scale of both corridors and sites.

Key words: Coral recruitment; Sulu Sea

Introduction

The Indo-Malay-Philippines "coral triangle" possesses the highest marine biodiversity in the world (Hoeksema 2007), and the Sulu Sea in central Philippines has among the highest concentrations of species per unit area in this region (Carpenter and Springer 2005). Reefs in the Sulu Sea are important not only for their high biodiversity and unique geology, but also as potential sources and sinks of larvae for other reefs, thus maintaining marine biodiversity in other Philippine inland seas (Alcala 1993). Understanding reef community dynamics, particularly recruitment processes, is crucial in determining reef recovery rates from perturbations due to human and natural disturbances (Hughes et al. 2005; Coles and Brown 2007).

Larval supply is determined by various factors, such as spawning season of adult coral species in the community and proportion of fecund adults (Hughes et al. 2000; Adjeroud et al. 2007). The amount and composition of larvae produced, however, can be very different from a reef's actual juvenile community structure. Studying larval settlement patterns may instead provide more insight into early recruitment dynamics. Coral recruitment patterns depend on a reef's physical and biological attributes, such as size (Glassom et al. 2006), morphology and existing community (Mumby et al. 2007; Norström et al. 2007; Perkol-Finkel and Benayahu 2007), as well as speed and direction of ocean currents. These influence how and where larvae are distributed, and eventually settle (Banks and Harriott 1996; Chen 1999; Taylor and Pearce 1999). The abundance and composition of recruits also change with increasing distance from the reef, a function of both current velocities and differing reproductive strategies among coral species (Sammarco and Andrews 1989).

This study sought to identify patterns in coral recruit abundance and composition in three Sulu Sea marine corridors at two spatial scales, i.e. within and among corridors. Possible physical and biological factors that might explain these patterns were investigated to gain insights on what processes influence the relative resilience and recovery of reefs from disturbances.

Material and Methods

Study site and data collection

The study was conducted in the major marine corridors of the Sulu Sea: Verde Passage in the north, Cagayancillo Islands and Tubbataha Reefs, comprising the Cagayan Ridge, in the central area, and Balabac Islands in the southwest (Fig. 1).

Approximately 16 terracotta tiles, each measuring 10 cm x 10 cm x 1.2 cm, were deployed along a 50-m transect in each of 33 sites. Sets of four tiles were nailed individually to the substrate at roughly 12-m intervals along each transect (Mundy 2000; Quibilan and Aliño 2004). The tiles were deployed at the onset of the northeast (NE) monsoon season in October 2006, and retrieved in April and May 2007, before the onset of the southwest (SW) monsoon season. Data gathered, therefore, represents recruitment for the NE

monsoon season. This season also covered the peak coral spawning months in the Philippines (Bermas et al. 1992; Atrigenio and Aliño 1994).

Upon retrieval, the tiles were air-dried, then examined under a stereoscope. The number of coral recruits on the top, undersurface, and sides of the tiles were counted and identified to family level according to the guide provided by Babcock et al (2003). Due to natural disturbances, not all deployed tiles were recovered.

Data analyses

Differences in mean recruit abundance at both site and corridor level were compared using the Analysis of Variance (ANOVA). Abundance data were fourth root-transformed prior to statistical analysis to conform to the Cochran C, Hartley, and Bartlett tests for homogeneity of variances. Tukey's Unequal N Honestly Significant Difference was used as post-hoc test.

To determine differences in recruit composition among sites and corridors, abundance data for each coral family were simultaneously compared among sites using the Analysis of Similarities (ANOSIM) based on the Bray-Curtis Similarity index (Clarke and Warwick 2001). Recruit density and composition data in each site were tested for correlations with geographical location and benthic composition of the surrounding reef using Pearson product-moment correlation, and Similarity of Percentages (SIMPER) based on Spearman rank correlations. Data collected by Deocadez et al. (this symposium's proceedings) on live benthic cover of the adult reef community using video transects was used for this analysis.

Results

Corridor Level

Mean recruit density was significantly higher in Balabac Islands than in the central corridors of Tubbataha Reefs and the Cagayancillo Islands (Fig. 2). Verde Passage did not differ significantly from either Balabac or Cagayancillo. Balabac also had the largest range in number of recruits per tile, while Tubbataha had the smallest (Fig. 2).

Pocilloporids dominated in Balabac and Verde, while acroporids dominated in the central Sulu Sea (Fig. 1). Poritids and other families each comprised less than 10% of recruits in all corridors. Sixty-nine percent of the recruits were found on the sides of the tiles, 19% on the undersurface, and 12% on the top. This trend was consistent in each corridor.

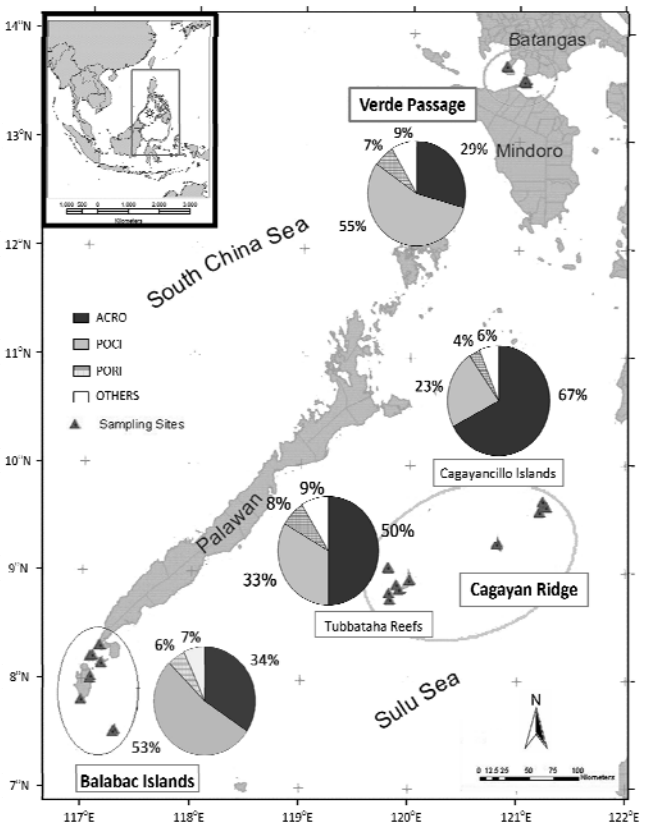

Figure 1: Location map of sampling sites with mean recruit density and composition per corridor. Each corridor spanned an area ranging from ≈300-3000 km^2, with Verde Passage being the smallest and Balabac Islands being the largest, due to its offshore islands. Adjacent corridors ranged from being ≈150-500 km apart. Each site covered an area of ≈100 m^2. Adjacent sites within corridors ranged from being ≈50 m-45 km apart. There were 6 sites in Verde, 8 in Tubbataha, 9 in Cagayancillo, and 10 in Balabac.

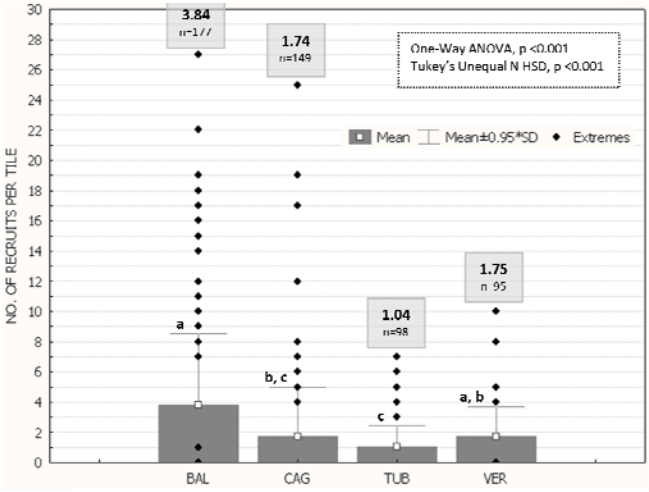

Figure 2: Mean recruit density with range of extreme values per corridor. Bars with the same letters are not statistically different.

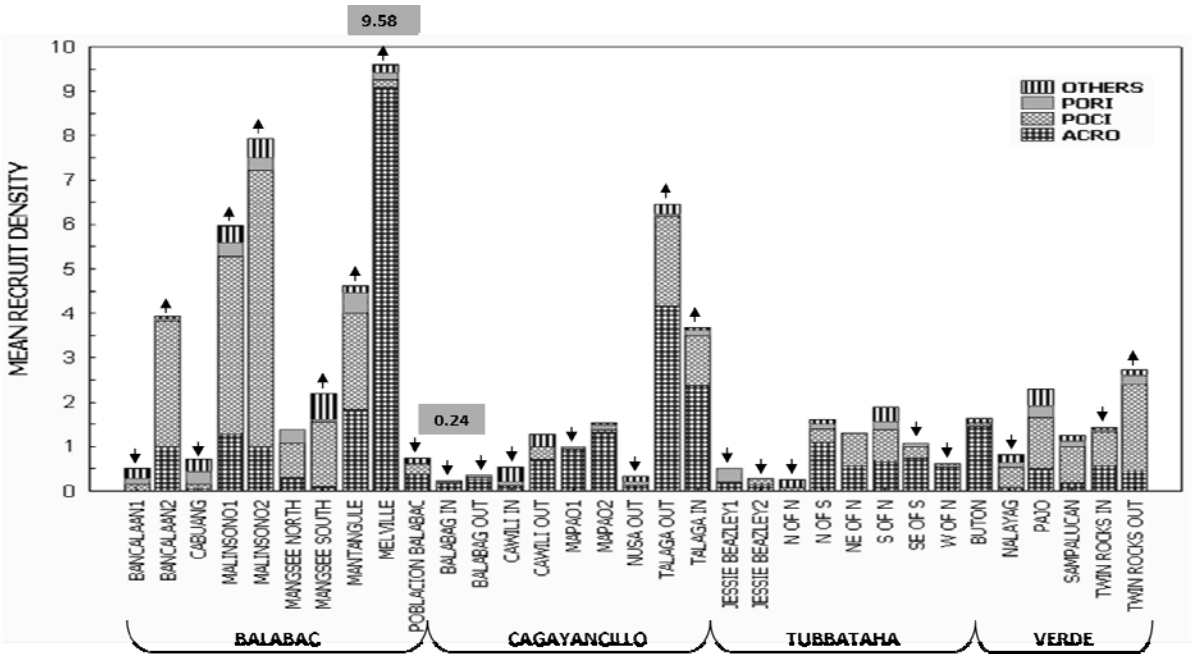

Figure 3: Mean recruit density and composition per site. Bars with up arrows indicate sites not statistically different from Melville. Bars with down arrows indicate sites not statistically different from Balabag In. Sites with no arrows are not statistically different from both Melville and Balabag In.

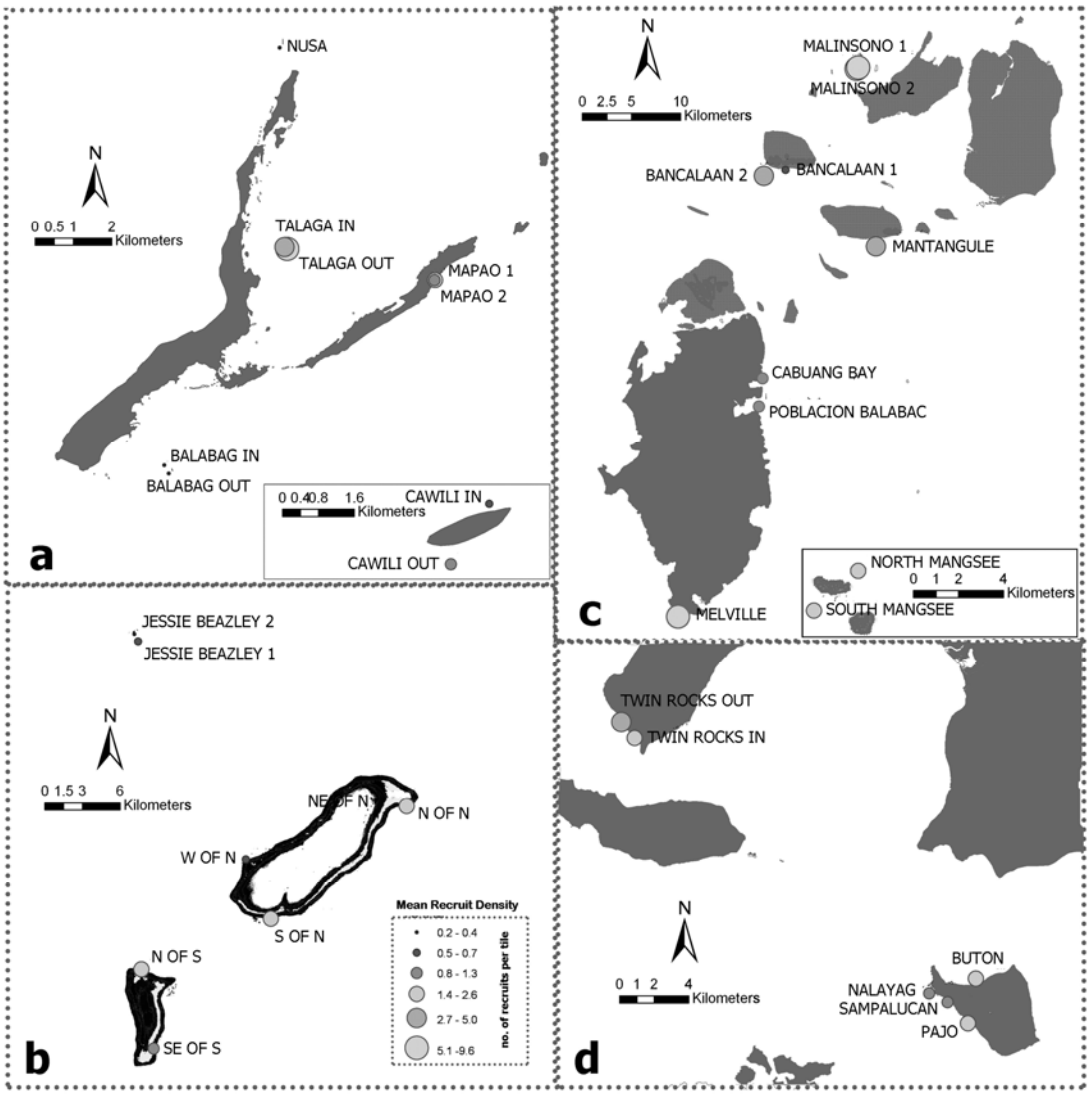

Figure 4: Map of mean recruit density per site, within corridors. a) Cagayancillo Islands [inset: Cawili Island, approx. 50 km SW] b) Tubbataha Reefs c) Balabac Islands [inset: Mangsee Islands, approx. 45 km SE] d) Verde Passage.

Site Level

Melville in Balabac had the highest mean recruit density among all sites (Fig. 3). Balabag In, found in Cagayancillo, had the lowest. Sites with high recruit density (i.e., not statistically different from Melville but statistically different from Balabag In) tended to be in areas between islands or in island wakes, with the possible presence of eddies (pers. observations from derived current circulation; see Vilanoy et al., this symposium's proceedings).

In Balabac, sites less than 500 m from the nearest shoreline (Cabuang, Poblacion, Bancalaan 1) had significantly lower mean recruit density than sites farther offshore. In the central Sulu Sea, outer reefs generally had lower recruit density than those closer to islands or other geological barriers. (Fig. 4)

Melville and Malinsono 1 in Balabac, and Talaga In and Out in Cagayancillo had significantly higher acroporid recruitment than all the other sites. Pocilloporid recruits generally dominated in sites on the western side of the islands, as opposed to the eastern side, in both Balabac and Verde (ANOSIM R=0.417, p=0.006). No apparent patterns in recruit composition were found in the central Sulu Sea sites in relation to their location on the reef.

Percent cover of adult *Acropora* along the transect, and the number of acroporid recruits on the tiles were not found to be correlated (Pearson product-moment correlation, r=-0.1172). Neither were recruit density and composition found to be associated with any other benthic category or with over-all benthic composition in each site (Spearman rank correlation, ρ_s=0.086).

Discussion

Differences in patterns of recruit abundance among the marine corridors suggest that individual physical factors have different degrees of influence on settlement rates. Distinct features of each corridor may magnify or reduce these effects.

Higher mean recruit density occurs in the Balabac Islands despite continuing destructive fishing activities. Contrary to this, Tubbataha Reefs and Cagayancillo Islands have relatively lower early recruit abundance despite being protected for years. Two factors may be most crucial: larval supply and entrainment potential.

Balabac is at the junction of two possible sources of coral larvae, the South China Sea and the Sulu Sea, which potentially increases its larval supply. Monsoonal wind-driven currents interacting with the relatively more complex configuration of islands in Balabac may result in the aggregation or entrainment of coral larvae, increasing their chances of settlement. As previously noted, sites with high recruit density, regardless of which corridor they were found in, tended to be between islands or in island wakes, which have high larval entrainment potential (Magno and Villanoy 2006). The greater number of islands in Balabac may also create more heterogeneous microhabitats with varying suitability for larval settlement, as suggested by the large range in recruit densities within this corridor compared to other corridors. This may explain why the Tubbataha Reefs and Cagayancillo corridors have the lowest mean recruitment, being reef slope sites located at least 200 km from other reef agglomerations, such as those in the Visayan seas and Palawan mainland.

Recruitment patterns differ between coastal waters and open seas because of very different hydrodynamics created by factors such as bathymetry and stratification nearer to shore (Pineda et al. 2007). Sammarco and Andrews (1988,1989) showed that highest recruitment occurs in the area of a reef with the lowest flushing rate. On the other hand, slower currents in inner reefs or the lee of islands tend to have higher sedimentation rates, which may inhibit recruitment (Murray et al. 1977; Connell et al. 1997). Ideal conditions for larval settlement may therefore be a complex topography that produces eddies which increase the larvae's residence time, in combination with strong currents that constantly flush out sediment. These findings highlight how major consideration must be given to current patterns in prioritizing sites for protection.

Apparent patterns in recruit composition at the corridor level (N-S) and site level (E-W) suggest that monsoonal wind-driven currents may determine the sources and sinks of larvae, depending on the site's geographical location in relation to the prevailing wind. Such monsoonal variation in recruit composition was observed in Palawan shelf reefs in the central Sulu Sea, where acroporids dominated during the SW monsoon, and pocilloporids during the NE monsoon (Quibilan and Aliño 2004). These patterns may also be due to seasonal currents interacting with species-specific peaks in coral spawning, as well as latitudinal differences (Hughes et al. 2002).

The lack of concordance between recruit and adult hard coral composition is not unusual, as seen in other studies (e.g. Banks and Harriott 1996; Hughes et al. 1999). This affirms the importance of post-settlement events in determining adult community structure following both anthropogenic and natural disturbances, such as crown-of-thorns outbreaks, storms and thermal anomalies resulting in bleaching (Arceo et al. 2001; Quibilan and Aliño 2004; Victor 2008).

Differences in coral-reef fish assemblages between mangrove-rich and mangrove-poor islands of Honduras

J.H. Harm[1], E. Kearns[2], M.R. Speight[1]

1) Oxford University, Department of Zoology, South Parks Road, Oxford 0X1 3JA, UK
2) Southampton University, National Oceanography Centre, European WY, Soton, SO14 3ZH, UK

Abstract. Visual surveys of coral-reef fish were conducted on two islands (and associated cays) off the Caribbean coast of Honduras, Cayos Cochinos (mangrove-poor) and Utila (mangrove-rich). Local populations on both islands exploit all marine habitats, and Utila suffers from higher fishing pressure compared to Cayos Cochinos, the latter having a conservation plan and no-take zones. Nine sites were visually surveyed in the mangroves to identify nursery species. Coral reef surveys consisted of eight randomly selected 50m transects at each site (six sites per island) where fish abundances, microhabitat percent cover, and rugosity were recorded. Findings from this study reveal that adult coral-reef nursery fish assemblages differ between the two islands. Out of 13 coral-reef fish whose juveniles are found in mangroves but absent from reefs, eight species had significantly higher adult coral-reef fish abundances on Utila than Cayos Cochinos. Canonical Correspondence analysis found that rugosity and percent algae explained a small but significant variation in fish assemblages. This correlation most likely explains the occurrence of increased adult non-nursery species abundance on Utila. However, a higher percentage of adult nursery species (compared to non-nursery species) had higher abundances on the surrounding reefs of Utila indicating the importance of the presence of mangroves.

Key words: Coral-reef fish, Mangroves, Nursery, Microhabitat.

Introduction

Shallow marine biotopes are thought to act as nurseries for many species of tropical fish (Dahlgren et al. 2006). Nurseries are believed to disproportionately enhance numbers of juveniles that move into adult habitats (Beck et al. 2001). Nursery reef fish species are species that are obligate to habitats other than coral reefs while in the juvenile stage. Studies have shown that mangrove and seagrass habitats provide vulnerable newly settled fish with appropriately sized food and refuge from predators (Laegdsgaard and Johnson 2001; Verweij et al. 2006).

Studies have focused on juvenile fish assemblages in mangroves and seagrass beds (Nagelkerken et al. 2000; Dorenbosch et al. 2006; Hindell and Jenkins 2004; Lugendo et al. 2006), and very few have actually compared adult populations in areas with and without mangrove nurseries (Nagelkerken et al. 2002; Mumby et al. 2004).

Past mangrove studies in the Caribbean have made pair-wise comparisons between two islands (mangrove-rich vs. mangrove-poor), to indicate the importance of mangroves as nursery sites. Island comparisons have shown higher abundances of nursery species on islands inhabited by mangroves (Nagelkerken et al. 2002; Mumby et al. 2004).

The aim of this study is to find which coral-reef fish juveniles reside in Honduran mangroves, and to compare these nursery species with control species (non-nursery) abundances between mangrove-rich and mangrove-poor islands. Previous studies have identified covarying factors that influence reef fish populations such as size of coral reefs and dominant coral species; however, this is the first study to include microhabitat variables of reef structure in influencing the adult fish structure. By including these variables, it will be possible to better isolate the importance of mangrove nursery grounds in determining adult reef fish populations**.**

Material and Methods

Study Area

Sampling and surveying were conducted on the surrounding reefs and mangroves of Utila, Bay Islands and the Cayos Cochinos Islands (Cayos C.), Honduras (Fig. 1). Utila, which has 13 cays, is the southernmost island in the Bay Island archipelago and is located 29 km off the coast of Honduras. Utila is dominated by mangroves (nearly 66% coverage). The mangroves, *Rhizophora mangle* and *Avicennia germinans,* dominate two large lagoons on the south side and mangrove stands on the north side of the island.

Cayos C. consists of Cayos Menor, Cayos Mejor and 13 smaller coral cays. The islands are located southeast of the Bay Islands, 18.5 km from the mainland. Tropical forests cover both Cayos Menor and Mejor, while most of the cays are sandbars. In contrast to Utila, Cayos C. has a distinct absence of mangrove lagoons and supports only two very small mangrove stands with lengths of 100 and 150 meters.

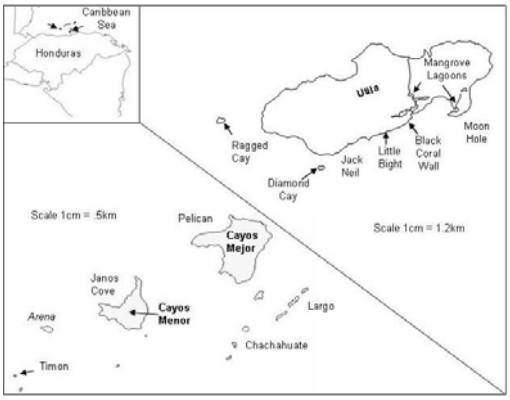

Figure 1: Map of Utila and Cayos Cochinos, Honduras, showing the 12 sites surveyed.

Fish surveys on coral reefs

This study used underwater visual census to make relative comparisons of fish abundances on both islands. Six sites per islands (Utila and Cayos C.) were surveyed. Sites were chosen based on three conditions (1) varying distance to mangroves, (2) reef flat shallower than nine meters (to eliminate any effects depth may have on fish assemblages), and (3) reef large enough to encompass replicate transects.

Within each site, eight non-overlapping 50 meter transects were laid out randomly (separated by >10m). Perpendicular distance and direction between transects were predetermined using random numbers. Each transect was laid out parallel to the reef wall, ensuring that the tape remained within a depth range between four and nine meters (local reefs form walls at depths greater than nine meters). Divers waited five minutes after deploying the tape for the fish to resume normal activity before beginning the survey (Tolimieri 1995). All fish (classified into life history stages), with the exception of small cryptic fish (e.g. gobies and blennies), were visually surveyed within one meter on each side of the tape (total width of 2m) and 2.5 meters above the tape. Life history stages (juvenile vs. adult) were defined by de la Moriniere et al. (2003) and FishBase (2008) (1/3 max adult size), while the initial phase stage was defined by distinct coloration differences (Humann and Deloach 2002).

Lutjanid, Chaetodonid, Haemulid, Scarid, and Serranid adults (large fish or fish with large home ranges) were resurveyed using a larger transect of five meters width. Previous to the study, divers spent two weeks practicing fish identification and experimenting with different transect areas to improve survey accuracy. Multiple divers were used only after survey records matched principle diver's records. Sites surveyed were rotated, to randomize diurnal and lunar variables. All surveys were performed between 0900 and 1600 to ensure consistency in fish activity and presence (Colton and Alevizon 1981).

Fish surveys in mangroves

To establish which coral-reef species use mangroves as a juvenile nursery (aka nursery species), nine mangrove sites (one on Cayos C., two on the northside of Utila, and six in Utila's western mangrove lagoon) were visually surveyed using snorkeling gear. In each site, 30x1m transects, with 10 meters separation, were measured out and marked with flagging tape before surveying.

Habitat and Rugosity

In order to provide insight into other potential mechanisms underlying anticipated differences in the fish communities between islands, microhabitat characteristics within every transect were measured using the point-contact technique (Caselle and Warner 1996). At every one meter interval on the tape, substrate type was recorded and live habitat was identified to species level (soft coral and algae were only identified to genus level due to lack of taxonomy expertise). Non-living habitat was recorded as sand, dead coral, or coral rubble (broken coral, mostly *Acropora* spp.)

Rugosity, a measure of the variation in height of physical surfaces along a linear extent of habitat, is often employed as one of the most important measurements of habitat complexity. On each transect, rugosity was measured using the traditional chain-transect method, laying a chain over the contours of the reef and measuring the resulting length (Risk 1972). The chain-transect rugosity is the ratio of contoured distance to the linear distance.

Analysis

Coral-reef fish assemblage of Utila and Cayos C. was analyzed using a Bray Curtis multivariate scatterplot and ANOSIM analysis from Community Analysis Package (Copyright Pisces Conservation LTD) statistical software. Data were first square-root transformed.

Fish abundances were statistically compared between Cayos C. and Utila. Comparisons were made using SPSS statistical software; a Mann-Whitney U-test was used on square-root transformed data.

One-way ANOVA, without data transformation was used to compare rugosity and microhabitat

percentages between the two island sets. In the case of significance, Bonferroni post-hoc tests were used to compare between sites. Canonical Correspondence analysis (CCA) and Monte Carlo tests (Environmental Community Analysis, Copyright Pisces Conservation LTD, statistical software) were used to compare microhabitat percent cover and rugosity to fish assemblages. To compare rugosity and microhabitat with abundances of individual fish species, Spearman-ranked correlations (SPSS) were used.

Results

Comparison of adult coral-reef fish assemblages between islands

Utila and Cayos C.'s multivariate plots of assemblages of fish nursery species on coral reefs show a significant difference (Fig. 2, ANOSIM, $p < 0.001$, $R = 0.104$) between the two islands.

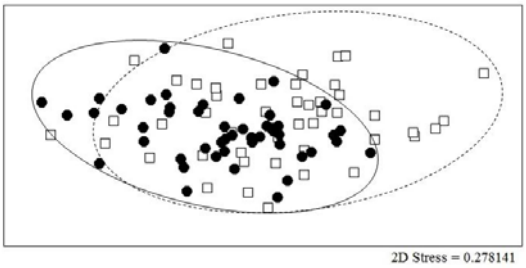

Figure 2: Multidimensional scaling ordination plot (Bray-Curtis dissimilarity coefficient) of fish assemblages (adult nursery species on coral-reefs) on Utila and Cayos C.
(□: Cayos Cochinos, ●: Utila).

Comparisons of average adult abundances on coral reefs (data from 5m transect width)

Of the 13 nursery species whose juveniles were found primarily in mangroves, eight fish species had significantly higher abundances on mangrove-rich Utila's coral reefs (Fig. 3). These species include butterflyfish *Chaetodon striatus* ($p < 0.01$), *C. capistratus* ($p < 0.01$), and *C. ocellatus* ($p < 0.001$), the parrotfish *Sparisoma chrysopterum* Initial Phase ($p < 0.05$), the snapper *Lutjanus apodus* ($p < 0.001$) and grunts *Haemulon carbonarium* ($p < 0.001$), *H. flavolineatum* ($p < 0.001$), and *H. sciurus* ($p < 0.001$).

These trends were present when broken down to site-to site comparisons. For seven species with significantly higher abundances, at least two sites on Utila (actual sites differed per species) had significantly higher abundances than three sites on Cayos C. ($p < 0.05$). *C. striatus* was the only species whose abundance showed no significant difference between Utila and Cayos C.'s individual sites.

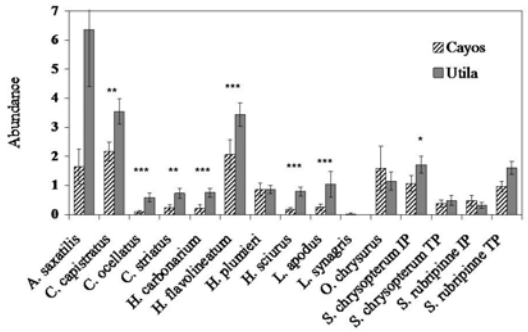

Figure 3: Average abundance per transect (±SE) of adult coral-reef fish whose juveniles were found in the mangroves. (*: $p<.05$; **: $p<.01$; ***: $p<.001$) (IP: Initial Phase; TP: Terminal Phase).

Comparing non-nursery and nursery species between islands

Some non-nursery adult fish species had higher abundances on Utila as well. However, a larger percentage of nursery species than non-nursery species had higher abundances on Utila (Fig. 4)

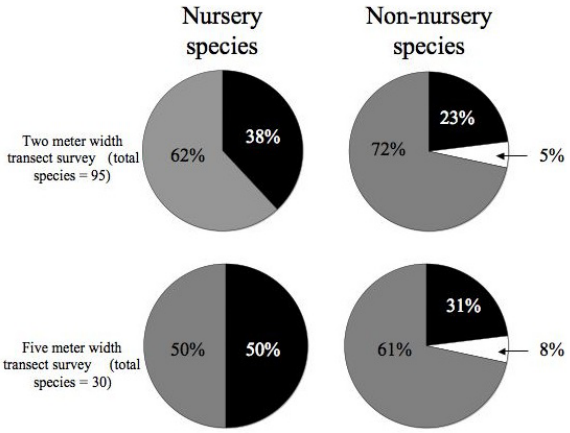

Figure 4: Pie charts depicting nursery and non-nursery fish abundance percentages for both the two meter and five meter width transect surveys (■ Percent species whose abundances were significantly higher on Utila , □ abundances lower on Utila, ■ No significant difference in abundances between Utila and Cayos C.)

Coral Reef Microhabitat and Rugosity

The point-contact microhabitat survey resulted in nine genera of algae, 13 genera of sponges, 17 genera of live hard coral, and eight genera of soft coral. Algae covered the largest percentage (Cayos C.: 40%; Utila: 33%) of transects on both islands; *Lobophora, Dictyota,* and *Halimeda* spp. dominated. Cayos C. had a significantly higher percentage of algae than Utila ($p < 0.05$), while Utila had a significantly higher percent cover of non-living coral than Cayos C. ($p < 0.001$). Percent cover of hard coral and soft coral, approximately 17% and 12% respectively, was not significantly different between the islands.

Average rugosity ratios for Utila and Cayos C. were 1.37 (SE ± 0.4) and 1.41 (SE ± 0.03),

respectively. Ratios between islands were not significantly different ($p = 0.370$). In addition, variation in depth (4-9m) produced no significant effects on fish assemblages.

Canonical Correspondence Analysis showed that algae (4.98% of variance) and rugosity (4.45% of variance) were the two best explanatory factors explaining variability in fish assemblages (see Fig. 5 for the ordination plot). Monte Carlo randomization tests demonstrated that the plotted axes were significant at the 0.05 level.

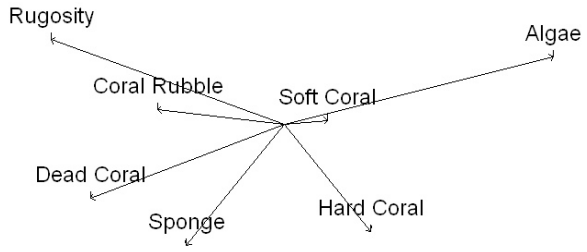

Figure 5: Canonical Correspondence Analysis Ordination plot of environmental vectors in correspondence to adult nursery fish assemblages. Length of vectors represents strength of explanatory variable, while direction of vector shows positive/negative correlation with other vectors.

Spearman-Ranked Correlations on substrate composition and rugosity did not reveal any clear correlations between these explanatory measurements and "mangrove-dependent" fish abundances with the exception of *Abudefduf saxatilis* (Utila and Cayos *C.* $p < 0$.051).

Discussion

Comparison of adult coral-reef fish assemblages between islands

Studies in Belize and Mexico found that the structure of Caribbean reef fish communities on reefs was significantly different between mangrove-rich and mangrove-poor sites (Mumby et al. 2004). These authors concluded that mangroves were the "dominant factor structuring reef fish communities."

Furthermore, the presence of mangroves in the Belize/Mexico studies were significantly correlated with the biomass of six species. *Scarus iserti* (striped parrotfish), *Haemulon sciurus* (blue-stripped grunt), *Haemulon flavolineatum* (French grunt), *Haemulon plumieri* (white grunt), *Ocyurus chrysurus* (yellow-tail snapper) and *Lutjanus apodus* (schoolmaster grunt) had biomass increases > 42% (Mumby et al. 2004). Two other studies have surveyed fish on coral reefs in the presence/absence of mangroves. In a study performed by Dorenbosch et al. (2003), sites adjacent to seagrass/mangrove bays had significantly higher densities of *H. sciurus, O. chrysurus* and *L. apodus.* Nagelkerken et al. (2002) compared fish assemblages on islands with and without nursery lagoon; *H. sciurus*, *O. chrysurus, L. apodus,* and *S. iserti* were highly dependent on mangrove nurseries. Likewise, the current study found significantly higher abundances of *H. sciurus, H. flavolineatum,* and *L. apodus* on Honduran reefs adjacent to islands with mangroves (Utila). *L. apodus* was the most common juvenile species found in the majority of mangrove studies performed in the Caribbean; therefore, mangroves have been deemed a vital habitat for this species (Nagelkerken et al. 2000; de la Moriniere 2003; Chittaro et al. 2005; and Verweij et al. 2006).

Since approximately 50% of the juveniles of *S. iserti* were found on coral reefs (53% on Cayos C., 40% on Utila) (data from surveys of 2m width transects), it was not considered to be a nursery species. Unlike previous studies, *S. iserti* adults were not found to have higher densities on mangrove-rich sites. In fact, their abundances were significantly lower at coral reef sites near mangroves.

Although Nagelkerken et al. (2002) concluded that *Chaetodon capistratus* and *Sparisoma chrysopterum* did not depend on mangroves, the present study found significantly higher abundances on Utila's coral reefs. Therefore, the dependence of these two species on mangrove nurseries is not a fixed factor. The current study also found significantly higher abundances of both *Chaetodon striatus* and *C. ocellatus* adults on the Utila. Nagelkerken et al. (2002) did not survey these two species. Nursery species *Abudefduf saxatilis, Haemulon plumieri,* and *Ocyurus chrysurus* were not significantly different between islands.

Coral-reef fish abundance explanatory variables

Although this study focuses on the positive effects mangroves have on nursery species abundances, many different explanatory variables (fishing pressures, rugosity, microhabitat, recruitment differences) may affect fish assemblages. Although local artisanal fishermen fish on both Cayos C. and Utila, Cayos C. has reduced fishing pressure due to a marine reserve conservation plan therein. On Cayos C., commercial fishing is illegal, fishing gear is regulated, and no-take zones have been established (Clifton and Clifton 1998). Therefore, it is unlikely that fishing pressure can explain decreased fish abundances on Cayos C.

In some studies, percent cover of live coral showed a significant positive correlation with fish species richness and abundance on shallow coral flats (Bell and Galzin 1984; Chabanet et al. 1997; Garpe and Ohman 2003). The current study, however, did not find a significant difference in live hard coral (average percent cover or species richness) between

islands or within sites. Therefore, this variable was not an important determinant of fish numbers.

However CCA ordination analysis shows that algae, which was significantly higher on Cayos C., and rugosity affect the nursery fish assemblages. In addition, results of the present study showed that the nursery species *Abudefduf saxatilis* was negatively correlated with algae on coral reefs. Further research must be implemented to study the negative correlation between *A. saxatilis* and algae.

Seven non-nursery species experienced higher abundances on Utila than Cayos C., which may be a result of these other explanatory variables. Regardless, it is important to emphasize that a larger percentage of nursery species had higher abundance on Utila than did non-nursery species. Therefore, comparisons between coral reefs off of mangrove-rich islands and mangrove-poor islands indicate that mangroves may increase the abundance of nursery coral-reef fish. This study adds one data point (island comparisons of fish nursery species) to a large scale graph of comparable matched-pairs from prior studies (four studies finding positive correlations between mangroves and adult coral reef fish and two showing no correlation (Halpern 2004, Nagelkerken 2007)) to give statistical power to comparing fish assemblages in the presence/absence of mangroves.

Abstract. During the last four years, quarterly visual censuses were conducted on reef communities at six sites around Bahía de La Paz (La Paz bay) using belt transects (10 × 1 m, n = 5 replicates per site). The present study documents the effect of one hurricane on the reef invertebrate's assemblage found at these sites by comparing community structure and abundance before and after the passage of hurricane John (September 2006, level II Safir/Simpson—winds of 215 km/h). On July 2006 (prior to the hurricane), visual censuses revealed 50 species and 3093 specimens, whereas in October 2006 (after the hurricane) 39 species and 2018 specimens were found, with a similarity index of 83.1% between these two surveys. There were 13 species that were not seen after the storm and three species were registered as "new" after the hurricane. The group most affected was the Echinoderms, with six species lost. The sighting of new species was mainly for the crabs, with two species. One year after the hurricane (October 2007), the recovery of the community was 38% of richness, with the addition of five species (three Echinoderms and two Mollusks) that were lost after the hurricane.

Key words: Monitoring, Reefs, Succession, Visual censuses.

Introduction

Marine invertebrates are important components in benthic communities where, among other functions, play an essential role by transferring energy up to higher trophic levels. For the Gulf of California, México, numerous studies on invertebrates have been conducted (i.e., Brusca 1980; Wicksten 1983; Villalobos et al. 1989; Hendrickx 1993). However, most of these papers were prepared under a taxonomic perspective and based on collections and voucher specimens from museums.

Bahía de La Paz (located in the southern Gulf of California, near the city of the same name) is probably the best studied location in the Gulf of California because of the presence of several marine sciences institutes in the area (Solís-Marin et al. 1997; González-Medina et al. 2006). Systematic checklists of different taxonomic groups such as fish (Castro-Aguirre and Balart 1997), echinoderms (Solís-Marin et al. 1997), mollusks (Holguín-Quiñones and García-Domínguez 1997), and decapods (Pereyra 1998; Hernández 1999) are available for this area. Many of these studies were performed on coral areas, where researchers used destructive methodologies to obtain specimens. These procedures were "acceptable" in the past, but after the mass mortality of corals occurred because of the increase in water temperature brought upon by the El Niño Southern Oscillation (Reyes-Bonilla 2001), there is growing concern that destructive sampling can exacerbate the natural degradation of these fragile systems. To avoid this problem, descriptive studies are now conducted chiefly using visual census methods.

The southern Gulf of California (where La Paz is) suffers the frequent impacts of hurricanes and tropical storms, but there are few studies on the damage that these disturbances exert on marine communities, and especially on the coral reefs of this area. Only Reyes-Bonilla (1993, 2003) and Glynn (2001) have provided information on this topic and described how hurricanes have actually caused limited damage to the urchin and fish populations; moreover, the hurricanes sometimes have even benefited coral dispersal by an increase in fragmentation. Considering the dearth of available information, the objective of this paper was to illustrate changes to the invertebrates' assemblages in coral habitats after the passage of a strong hurricane. Our results show how the impacts were immediate and sustained, as one year after the perturbation, the assemblages had not returned to their original state.

Material and Methods

Bahía de La Paz is located in the southwestern Gulf of California between 24° 11´ to 24° 40´N, and 110° 20´ to 110° 42´W. On September 2006, hurricane John (level II Safir/Simpson—winds of 215 km/h) impacted the area (Fig. 1) and caused severe disturbance to the benthic communities along its path. In the present study, surveys were conducted in July 2006 (before the hurricane), October 2006 (after the hurricane), and one year after the event (October 2007), in order to measure the impact and potential recovery of invertebrate assemblages.

Surveys were conducted on coral reefs or communities (sensu Reyes-Bonilla 2003) at four sites using belt transects (10×1 m, n = five replicates per site). A SCUBA diver visually identified and counted the invertebrates seen inside the belts. The taxa surveyed included mollusks (Gastropoda), sea urchins (Echinoidea), sea stars (Asteroidea), decapod crustaceans (Anomura, Brachyura, and Caridea), and polychaetes (Annelida). From these records, several community descriptors (Magurran 2003) were calculated to compare the structure of the communities over time [similarity (Bray-Curtis coeff-

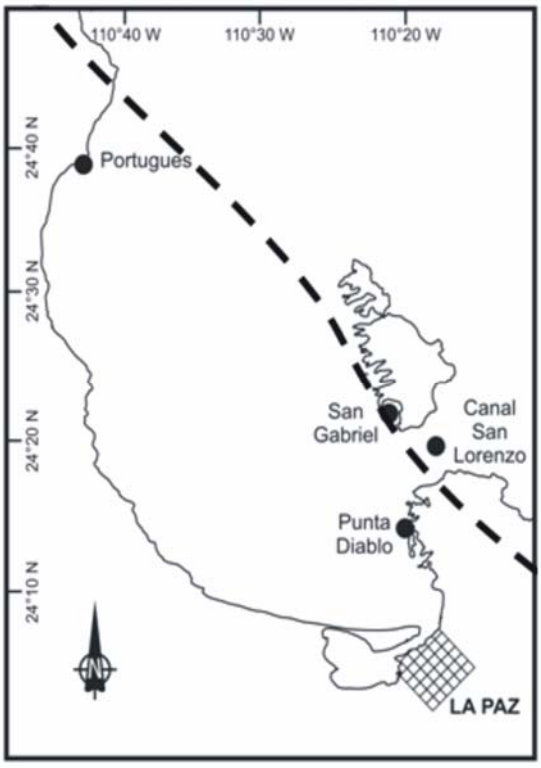

Figure 1: Study area (Bahía de La Paz) and survey sites. The dashed line shows the trajectory of hurricane John (August-September 2006).

icient), diversity (Shannon-Wiener index), and evenness (Pielou index)]. We used a non metric multidimensional scaling (Clarke and Gorley 2006) to map the degree of similarity among sampling sites (before, after, and one year after the hurricane). A cluster analysis was applied to view the similarities in species richness among sampling dates (July 06, October 06, and October 07). Comparisons among surveys at each site were done using 1 way ANOVA.

Results

Species richness and abundance of invertebrates decreased after the passage of the hurricane; the change was remarkable as these descriptors were down from 20% to 30% of initial (Table 1). In contrast, the diversity and evenness practically remained the same. To confirm that changes were caused by the hurricane and do not represent the seasonal variation, we plotted the annual density on July and October from 2005 to 2007 (Fig. 2). In the graphic is evident that the average density on October 2006 was lower than in 2005 and 2007 and the difference is statistically significant ($F= 4.94$, $p<0.05$). This found represents the hurricane effect on the invertebrates' assemblage.

Table 1. Community parameters of invertebrates' assemblage in La Paz bay before and after hurricane John (S= species richness; N= abundance, J´=evenness, H´= diversity).

	S	N	J´	H´
July 06 (Before)	50	3093	0.94	3.67
October 06 (After)	39	2018	0.96	3.51

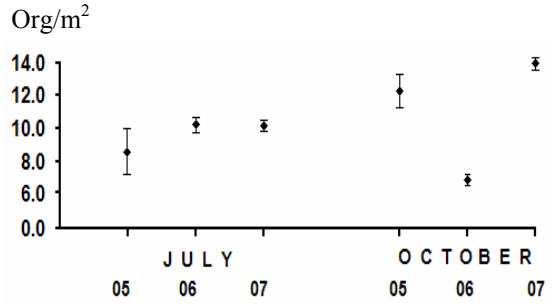

Figure 2: Density of invertebrates including the same months one year before and one after the hurricane, to show annual tendencies. (average ± standard deviation).

There were also changes in species composition. Fourteen species found before the hurricane (July 06) were not observed after the storm (October 06). The most sensitive group was the echinoderms with seven species lost (i.e. *Amphiaster insignis, Euapta godefroyi, Isostichopus fuscus*) followed by mollusks with five species (i.e. *Megapitaria squalida,*

Muricanthus nigritus, Nodipecten subnodosus), and crustaceans and annelids with one species each.

On the other hand, Crustaceans practically did not change in abundance from 897 individuals before the hurricane, to 908 just afterwards. Remarkably, their numbers rose to >2500 individuals one year after the perturbation. Within this group, the opportunistic, coral-symbiotic crustacean species were the most abundant (Table 2).

Table 2. Abundance of most sensitive species before and after hurricane John (July 06 vs. October 07). Groups: Cru =Crustaceans, Ech = Echinoderms, Mol =Mollusks. * = Symbiotic to pocilloporid corals.

Group	Species	Jul 06	Oct 07
Cru	*Alpheus lottini**	191	488
Cru	*Calcinus californiensis*	22	61
Ech	*Diadema mexicanum*	123	18
Ech	*Echinometra vanbrunti*	319	89
Cru	*Harpiliopsis depressa**	192	718
Cru	*Harpiliopsis spinigera**	80	507
Cru	*Neaxius vivesi*	58	2
Mol	*Quoyula madreporarum**	30	115
Cru	*Trapezia ferruginea**	251	538

A comparison of similarity among sites based on species composition and abundance was performed whit data taken just after de hurricane (October 06). The community at San Gabriel reef was very different from the rest, although this difference was not significant (stress > 0.10: Fig 3).

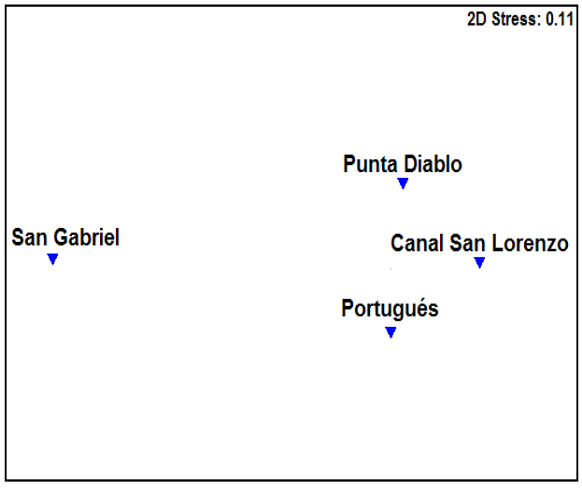

Figure 3: nMDS of invertebrates' abundance on the sampled sites.

Comparisons over time indicated that species richness after the disturbances (October 2006 and October 2007) were more similar between them, than those sampled prior to the storm (Fig. 4).

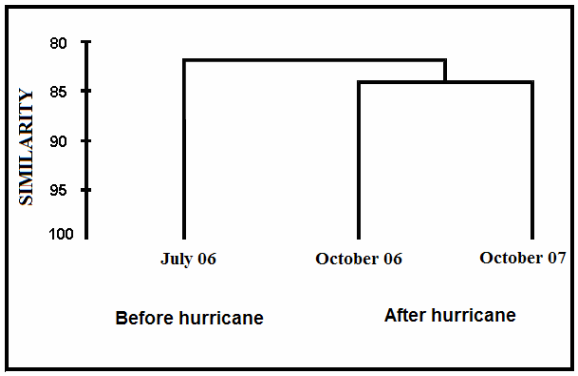

Figure 4: Similarity cluster (Bray-Curtis) on species richness of invertebrates from Bahía de La Paz before and after hurricane John.

Discussion

The present study showed that community parameters changed after the hurricane. Commonly, after any disturbance in this kind of ecosystems, dominance decreases and diversity increases (Rogers 2003). However, in the present study, we detected important changes in richness and abundance, whereas evenness and diversity remained at similar levels. The slight increase in equitability (Table 1) was maybe related to a more equal distribution of abundance among the species, caused by the change in the substrate heterogeneity promoted by the storm. However, in the present study diversity and evenness did not change significantly with time. As these markers are defined by an interaction of richness and relative abundances (Salazar-Vallejo 2002), we suggest that species replacements after the hurricane may have caused the detected stability.

The physical damage caused by hurricanes can be considerable. Lugo-Fernández et al. (1994) showed that waves were the main agent that caused changes in Margarita reefs (Puerto Rico). At San Gabriel, coral pieces broken by the hurricane covered the sandy-gravel bottom and, thus, caused some sedentary species to be removed, including the clams *Megapitaria squalida* and *Nodipecten subnodosus*. On the other hand, organisms that are usually not seen in visual surveys (i.e., the crab *Eriphia squamata*, the clam *Pinna rugosa*), were exposed by the broken corals after the hurricane (October 2006). Notwithstanding the higher probability of observing specimens, richness was still lower than before the storm (July 2006). Thus, the hurricane caused an immediate greater impact on species richness, and also qualitatively changed the community.

In addition, coral fragmentation caused by the hurricane at San Gabriel promoted an increase in availability of coral substrata and, as a consequence, there was an increase in abundance one year after the

storm compared to previous dates. Interestingly, most of the higher abundances were due to the arrival of coral-symbiotic species (Table 2).

One year after the hurricane John (October 2007), there were numerous echinoderm and mollusk recruits, which will likely recover baseline conditions in the reef areas visited. Rogers (2003) stated that the recovery of any community will depend, on the natural resilience of the species that compose the community. In the case of La Paz, there were no hurricanes of consideration in 2007 and 2008; if this trend continues, it is feasible that the conditions may improve in years to come. In the absence of storms, an increase in the abundance and richness concomitant with a less homogeneous community where the dominant taxa will regain their advantage would be expected.

In the present study, the before-after comparison was accomplished thanks to a monitoring program that was initiated in 2005 using methods that do not disturb the corals and associated fauna (Halford and Thompson 1994). Visual surveys present advantages over destructive techniques in the study of disturbed areas, as the corals suffer no further harm. Finally, the results presented here serve as a baseline inventory of coral-associated invertebrates for future evaluations. The data collected will also help local environmental authorities in the monitoring and management of protected areas, especially considering that San Gabriel reef is now part of a recently established National Park.

Carry-over effects - the importance of a good start

M. I. McCormick[1], M. Gagliano[1,2]

1) ARC Centre of Excellence for Coral Reef Studies, and School of Marine and Tropical Biology, James Cook University, Townsville, Queensland 4811, Australia
2) Australian Institute of Marine Science, Townsville, Queensland 4810, Australia

Abstract. Every organism has a history and its past experiences shape its present capabilities and may greatly influence the outcome of future events. For marine organisms with complex life cycles, seemingly discrete life stages separated by periods of rapid change (metamorphosis) have led researchers to focus on processes that occur within stages. Recent research highlights the interconnections among life stages and underscore that phases within a life cycle are functionally coupled. Success in one stage biases the probability of outcomes in subsequent stages. The present study reviews research on model species of tropical reef damselfish, *Pomacentrus amboinensis*, to highlight the fundamental importance of effects that 'carry-over' from previous life stages and potentially generations. Research strongly suggests that the physiological state of parents (particularly mothers) during gametogenesis pro-rate offspring success and may even influence their fitness.

Key words: parental effects, metamorphosis, coral reef fish, history, phenotypic selection

Introduction

The life cycles of marine organisms are comprsed of a series of discrete life stages. Transitions between stages differ in their nature and the magnitude of change and are species specific. Each life stage will have a different primary role (development, growth, recruitment, reproduction), and will be responsive to, and affected by, prevailing conditions differently. Because of the dramatic changes in function, physiology and environment that characterize sequential life stages it cannot be expected that advantages gained in one life stage (e.g. the ability to capture planktonic particles) will necessarily result in an advantage in the next stage. However, recent evidence suggests that the way individuals respond to conditions in one life stage can influence their characteristics in subsequent life stages. Individual characteristics of one particular life stage have been found to positively influence the next life stage, but they can also influence multiple life-stages and even may extend between generations (Green and McCormick 2005; Giménez 2006).

Because the intensity of selection on phenotype, life history or behavioural traits will change with ontogeny it is important to know the extent to which an individual's characteristics are influenced by its history and the extent to which its success is independent of past events.

How an individual's history influences present and future outcomes, now known as 'carry-over effects', has recently become a focus of interest for marine researchers. Researchers on invertebrates in particular have recently focused attention on the links between life stages (Podolsky and Morany 2006 and references in same issue), possibly because of the greater ease of laboratory rearing and relatively short longevities of invertebrates. Researchers on fishes have typically underplayed the importance of life history interconnections, despite a large body of research from a diverse range of fields that underscores their importance.

Our objective is to highlight the importance of carry-over effects to coral reef fishes by briefly reviewing research on one Indo-Pacific damselfish (*Pomacentrus amboinensis*) that has been used as a model for many different types of biological, ecological and evolutionary studies. Using these studies we emphasise the interconnection among life stages and the ramifications of these for population dynamics. The link between the quality and performance traits of fish and their numerical population consequences has been explored elsewhere (Jones and McCormick 2002).

Parental influences on larval traits

Recent research suggests that parental attributes of coral reef fishes greatly influence developmental and performance trajectories of larvae through the provisioning of the gametes during gametogenesis, as shown in other organisms (Mouseau and Fox 1998). Studies of *P. amboinensis* have emphasized the importance of maternal body condition and physiological state in influencing embryo and larval phenotype, with female

effects being stronger than male effects (Table 1). A study that monitored the reproductive output of 40 breeding pairs on 2x2m patch reefs found that females of smaller size that were in better than average body condition produced larvae that had larger nutritional stores (Table 1), while female age had little influence on larval attributes at hatching. When females were placed into three size categories it was evident that small females produced larvae that were both longer and had larger yolk-sacs at hatching (Table 1).

Table 1: The influence of female and male *P. amboinensis* attributes on larval morphology at hatching, from breeding pairs on 40 patch reefs in the Lizard Island lagoon, Great Barrier Reef (GRR). Significant partial correlations are given; ns indicates no significant relationship between the two variables at α=0.05. Condition of females (cond) was quantified as the residuals of a length/wet weight regression. Females ranged between 40.8 to 66.4mm standard length, and were 2 to 6 years old. n = 25 per comparison. Larvae were preserved and measured as per McCormick (2006) and aged following Maddams (2007). Larval attributes are for the second clutch produced. Source: Maddams and McCormick unpublished.data.

Experiments that supplementary fed breeding pairs in the field have shown that maternal body condition influences the yolk-sac size of larvae at hatching, but has little influence on larval length (Kerrigan 1997; McCormick 2003; Fig. 1).

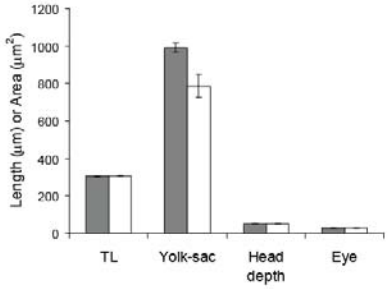

Figure 1: Comparison of morphologies of larvae at hatching from *P. amboinensis* breeding females that have (grey) or have not been supplementary fed (white bar) in the field for 5 min per day (from McCormick 2003). Errors are standard errors.

In contrast, parental interactions that alter maternal stress levels, such as density-dependent interactions with con- or hetero-specifics, directly influence larval length at hatching through a mechanism involving the stress hormone, cortisol (McCormick 1998, 1999, 2006, 2009; McCormick and Nechaev 2002). Experimental manipulations of maternal cortisol within naturally occurring limits were able to produce larvae that spanned the complete size range that naturally occurred in the wild, emphasizing the importance of this mechanism (McCormick 1999, 2006). Interestingly, laboratory manipulations of maternal testosterone were found to influence yolk-sac utilization rates.

Maternal stress has also been shown to influence the inter-relationships among early life-history traits in *P. amboinensis*. By manipulating the cortisol environment of individual embryos, Gagliano and McCormick (unpublished data) have been able to show that the fundamental relationship between early life history traits changes, emphasizing the potent role of the maternal state at gametogenesis for subsequent larval performance and survival (Fig. 2). Laboratory manipulations of cortisol and testosterone have previously been shown to influence the relationship between larval standard length at hatching and yolk sac area (McCormick 1999).

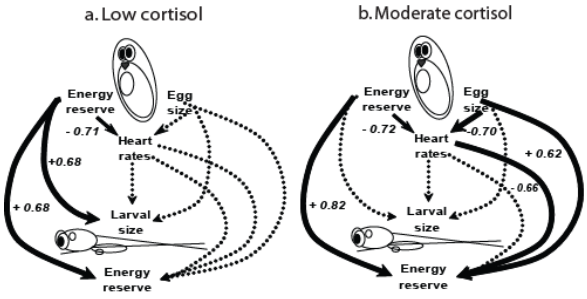

Figure 2: Summary of the correlations among early life history attributes of *P. amboinensis* embryos at 36 h post-fertilization (pf) with heart rate at 84 h pf and attributes of newly hatched larvae. Correlations for embryos incubated with no additional cortisol added to seawater (a) are compared to embryos incubated in seawater supplemented with a cortisol solution (10^2 ng/ml) to mimic moderate levels of maternal interactions (b). Protocols followed McCormick (1999) and Gagliano et al. (2007b). n=72. Bold lines represent significant relationships.

Similar laboratory manipulations have indicated that aspects of the sensory system are also influenced by maternal stress. Recent experiments found that maternal stress directly influenced the fluctuating asymmetry (FA) of the sagittal otoliths (Gagliano and McCormick submitted). A field experiment showing the relationship between otolith asymmetry and attraction to specific sounds suggests that FA may be important in navigation (Gagliano et al. 2008). There is also the indication from field data on *P. amboinensis* (Gagliano and McCormick submitted) and on a tropical lizardfish (*Saurida suspicio*) (Lemberget and McCormick 2009) that larval survival is directly and strongly related to the degree of otolith FA. These studies directly link larval survival and cohort strength to maternal influences.

Initial characteristics influence larval and juvenile survival

The ubiquitous problem of collecting identifiable larva at anything other than the start or end of their larval stage has made studying the processes that influence survival difficult for tropical marine organisms. This has meant that much of the research conducted on fish larvae to date has examined the Olympians that survived the larval phase. From these we attempt to make inferences on the processes that facilitated their survival, and what influenced those that died.

In the most comprehensive study to date, Gagliano et al. (2007a) serially sampled a pulse of *P. amboinensis* from production through to 2 months post-settlement (ps) and examined phenotypic selection using the history of growth stored in otoliths. They found strong links between early life history traits and persistence, with even the earliest traits, such as size of the sagittal otolith at hatching, still being selected for well into the juvenile phase (Table 2). Of the diverse traits measured, growth during the larval phase was the trait with the longest duration of influence, with selection still being detectable 6 weeks into the juvenile phase (Table 2).

Table 2: Carry-over effects of (a) phenotypic traits, as represented by otolith size, and (b) otolith growth on subsequent survival from serial samples of a reproductive pulse of *P. amboinensis* from Lizard Island, GBR. Summary indicates the duration that selection on various attributes is detectable and the direction of that selection. ns, no significant selection. (*after* Gagliano et al. 2007a).

First 2 wks ps	3 wks ps	+
Third wk ps	4 wks ps	-
Forth wk ps	ns	

Field and laboratory experiments have shown that settlement represents a critical phase for *P. amboinensis* with mortality showing a Type III trajectory and being highly selective for a variety of traits (McCormick and Hoey 2004). Overall, fish that were larger at settlement, that had larger lipid stores and who had higher larval growth, had a survival advantage (Table 3). The attributes that influence *P. amboinensis* survival at settlement are, however, dependent upon the location they settle into and the resident community at that location (Holmes and McCormick 2006).

A field experiment by McCormick and Meekan (2007) showed the characteristics that influence prey survival were dependent upon the patch-work of predator selection-fields into which the naïve juveniles settled. Juveniles that settled into nesting

Table 3: Summary of the selectivity of mortality on various phenotypic attributes for newly settled *P. amboinensis* that were naïve to predators. A positive selection direction means that individuals that had a larger value on that trait had a higher probability of mortality. In the laboratory trials the dottyback, *Pseudochromis fuscus*, was used. Laboratory and field trials with weight and burst speed were size standardized. ns, non-significant effect. FA: fluctuating asymmetry. territories of male *P. amboinensis* were exposed to positive selection by the dottyback *Pseudochromis fuscus*, which prefers large recruits and who were not evicted by aggressive male territory holders. Outside the territories, where the juveniles were exposed to a broader range of predators, larger individuals had higher survival.

Initial larval characteristics influence individual fitness

Recently, studies of marine organisms have found a link between early life history traits and adult success. Many tropical fishes exhibit complex ontogenies involving sex change. The most common form is protogyny, where juveniles first mature as females and then undergo sex change in the event of the appropriate social trigger (monandric protogynous hermaphrodism; Munday et al. 2006). In these species, individuals that attain the status of male get to monopolise matings and have the highest fitness. *P. amboinensis* is a damselfish that exhibits protogynous hermaphrodism. Male and dominant female *P. amboinensis* were collected from around Lizard Island and growth histories were reconstructed using otolith increment widths from cross sections of the sagitta as a proxy for growth. For a portion of these fish (up to 7 years old) it was possible to obtain measurements from the larval otolith. Those females that had undergone sex change and became males were found to have significantly smaller increment widths compared to those that were still female ($t = 2.32$, df 11, $p = 0.04$; Fig. 3). Of the six other species from 2 families that we have examined, 3 have shown similar relationships, with significant differences in larval growth starting with the hatch mark, between females and those fish that become males later in life (1 out of 2 sandperches, 2 out of 4 wrasse; Walker et al. 2007; McCormick and Ryen unpublished data).

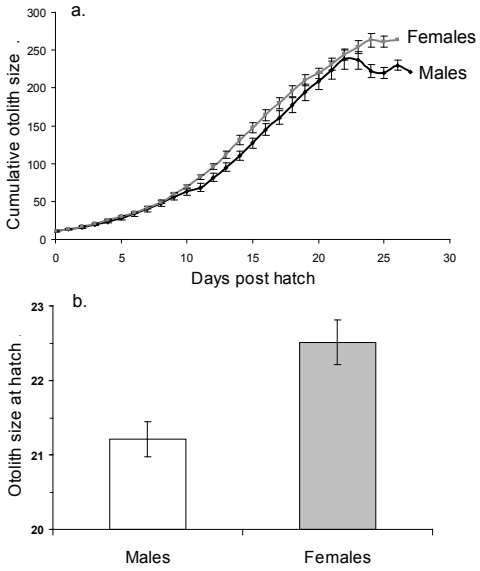

Figure 3: Early otolith growth of females and females that have changed sex to become males showing cumulative otolith growth through the larval phase (a), and differences in increment widths between sexes at hatching (b). Errors are standard errors (n = 8 females and 5 males).

Transgenerational effects

The pelagic larval phase of almost all coral reef fishes makes it difficult to track the fate of individuals from when first produced from parents of known history through to becoming an old member of a reproductive group (i.e. one with measurable fitness). While transgenerational studies are presently being conducted on a brooding

species (*Acanthochromis polyacanthus*; e.g. Donelson et al. 2008), the rarity of the strategy to have non-dispersive larvae means that results, whilst useful, will have limited applicability to the population dynamics of most marine fishes. We must therefore make the best of inferences we can make on the connections between generations.

Otoliths are a valuable record of relative growth and may prove a useful tool in linking parental influences to the growth dynamics of their offspring. Unfortunately, while we know that the relationship between somatic growth and otolith growth can be individualistic (Campana and Jones 1992), we have little understanding of the plasticity of the relationship, the factors that will influence it and the potential lag effects for most life stages of fish (see Molony and Choat 1990 for juveniles). A recent study that has simulated the effects of maternal stress on the embryogenesis of individual *P. amboinensis* found that maternal cortisol levels not only influenced the strength of the relationship between early life history traits, but influenced the fundamental relationships between phenotypic traits and otolith size at hatching (Table 4). Under a low stress scenario, otolith size at hatching was negatively related to initial and hatching yolk size and to heart rate (at 84h post-fertilization; a proxy for metabolism). This is opposite to the relationship found for 7 juvenile freshwater pike, where metabolism was positively associated with the width of increments deposited (Armstrong et al. 2004). Interestingly, when simulated maternal stress increased, the relationships between early life history attributes changed. It was only under moderate levels of stress that a positive relationship was found between otolith size at hatching and larval length (Table 4). It is this positive relationship between otolith size and larval size that is often assumed to be present in previous studies (Vigliola and Meekan 2002). Clearly further work is required to determine the drivers of increment width.

Table 4: Relationship of otolith (sagitta) size at hatching with early life history attributes for *P. amboinensis* embryos individually reared from fertilized eggs under three simulated maternal stress levels. Low stress (no addition of cortisol, equivalent to parents being on a patch reef alone); Moderate stress (addition of low cortisol dose, equivalent to the mother interacting with 2 conspecifics on a patch reef); High stress (high cortisol dose, equivalent to the mother interacting with 4 to 6 other conspecifics on a patch reef). For detailed methods see Gagliano and McCormick (submitted).

	Otolith size at hatch versus			
Treatment	Yolk size of egg	Heart rate	Yolk size at hatch	Length at hatch
Low cortisol	-0.71	-0.78	-0.69	ns
Mod cortisol	ns	ns	ns	+0.63
High cortisol	-0.88	ns	ns	ns

While the exact meaning of the otolith size at hatching is presently unclear, evidence suggests that maternal effects are likely to have a major influence on the relationship between early life history traits and otolith characteristics. The relationship between initial otolith size and fitness, together with the influence of maternal stress on larval size and otolith FA (McCormick 2006; Gagliano and McCormick submitted), suggest that maternal characteristics may play an important role in predetermining the subsequent fitness of individuals; the ultimate carry-over effect.

Carry-over effects have been documented in many marine phyla. There are many studies of fish that have shown that previous history influence future success (Berkely et al. 2004; Sponaugle and Grorud-Colvert 2006). These links occur between adjacent life-stages, across multiple stages and across generations. To date, few marine studies have managed to demonstrate transgeneration effects because of the logistical difficulties in linking all the stages in organisms with complex life cycles. Available data, such as that compiled here for one model fish species, suggests that transgenerational effects may be very important in influencing population dynamics. The key is to focus attention on how an individual's history influences present and future outcomes. The recent findings of high levels of self replenishment on small spatial scales for reef fishes with substantial larval durations (Almany et al. 2007) opens up additional possibilities for rapid local scale adaptation to changing conditions through maternal effects. The strong physiological, developmental, behavioural and performance links between stages and potentially between generations, mean that carry-over effects are fundamental forces that have been important in the shaping of existing populations and communities. The challenge is to define the extent to which carry-over effects influence present day dynamics and their importance in ecological and evolutionary time scales.

Abstract. To understand the current community structure on reefs in the Dry Tortugas, we conducted species-level surveys of macroalgae, coral diversity, herbivorous and game fishes, urchins, and substratum composition (e.g., rugosity) in shallow (3- to 5-m depth) low-relief reef and hardbottom habitats in October 2007. We had particular interest in the ecological process of herbivory inside and outside of the "no-take" Research Natural Area (RNA) designated by the U.S. National Park Service in 2007, and establishing a baseline to assess future changes to trophic functioning. *Diadema antillarum* and herbivorous fish abundance, percent cover of macroalgae, and species richness of corals and gorgonians at the 18 randomly selected survey sites were not significantly different inside vs. outside of the RNA. Mean densities of *D. antillarum* ranged from 0.01 to 0.54 individuals m^{-2}, with 11 of the 18 sites having densities above 0.10 individuals m^{-2}. Both *D. antillarum* density and coral species richness were positively correlated to rugosity of the substratum. *Diadema antillarum* density was also positively related to percentage of the substratum composed of *Acropora cervicornis* rubble. Improved trophic functioning and increases in *D. antillarum* can improve reef condition in the Dry Tortugas, and the RNA is an important management tool to achieve increases in reef resilience to global-scale stressors.

Key words: community structure, urchins, herbivory, marine protected areas, marine reserves, *Diadema*

Introduction

The Dry Tortugas is a unique and isolated atoll-like reef system at the terminus of the Florida Keys. Like other reefs in the Florida/Caribbean region, this area has experienced significant community shifts indicative of degradation, with reduced live coral coverage, increases in macroalgae, and decreases in species targeted in fisheries. However, both local and global stressors probably contributed to these community shifts, and meteorological events are known to have impacted the reefs. Reef research has a fairly long history in the Dry Tortugas, beginning before the establishment of the Carnegie Institute Tortugas Laboratory on Loggerhead Key in 1905 (Davis 1982; Shinn and Jaap 2005). Alexander Agassiz mapped the Dry Tortugas benthos in 1881 (Davis 1982), showing tens of hectares of *Acropora palmata*, but coring has revealed that this species was not responsible for reef accretion in the Dry Tortugas (Shinn et al. 1977). In 1976, a comprehensive habitat map was created to examine community change since the Agassiz map, showing that the *A. palmata* had all but disappeared and that *A. cervicornis* coverage was vast (Davis 1982). In January 1977, a severe cold front killed most of the *A. cervicornis* reefs in the Dry Tortugas (Davis 1982; Porter et al. 1982). Populations have not recovered on patch reefs once dominated by this species in the early 1970s; in fact, a representative site showed continued decline from 1999 to 2005 due to bleaching and disease (Beaver et al. 2005).

The purpose of our study was to characterize the current biological communities within Dry Tortugas National Park to provide important baseline data for assessing the effects of the "no-take" Research Natural Area (RNA) designated by the U.S. National Park Service (NPS) in 2007. We also sought to document any recovery of populations impacted during documented disturbances (Porter et al. 1982; Beaver et al. 2005), and to assess the ecological process of herbivory inside and outside of the RNA prior to any RNA-induced changes to trophic structure that may occur due to the new management regime. Because of our interest in herbivory, and because most other monitoring programs (e.g., NPS-South Florida/Caribbean Inventory and Monitoring Network, National Oceanic and Atmospheric Administration, NPS-DTNP and Florida Fish and Wildlife Research Institute) have focused on habitat > 6 m, we chose to focus our study on the shallow (< 5 m) reef environment. Recovery rates of the benthic community can increase within well-enforced marine protected areas (Mumby et al. 2006; Hughes et al. 2007); our long-term goal is to test this hypothesis.

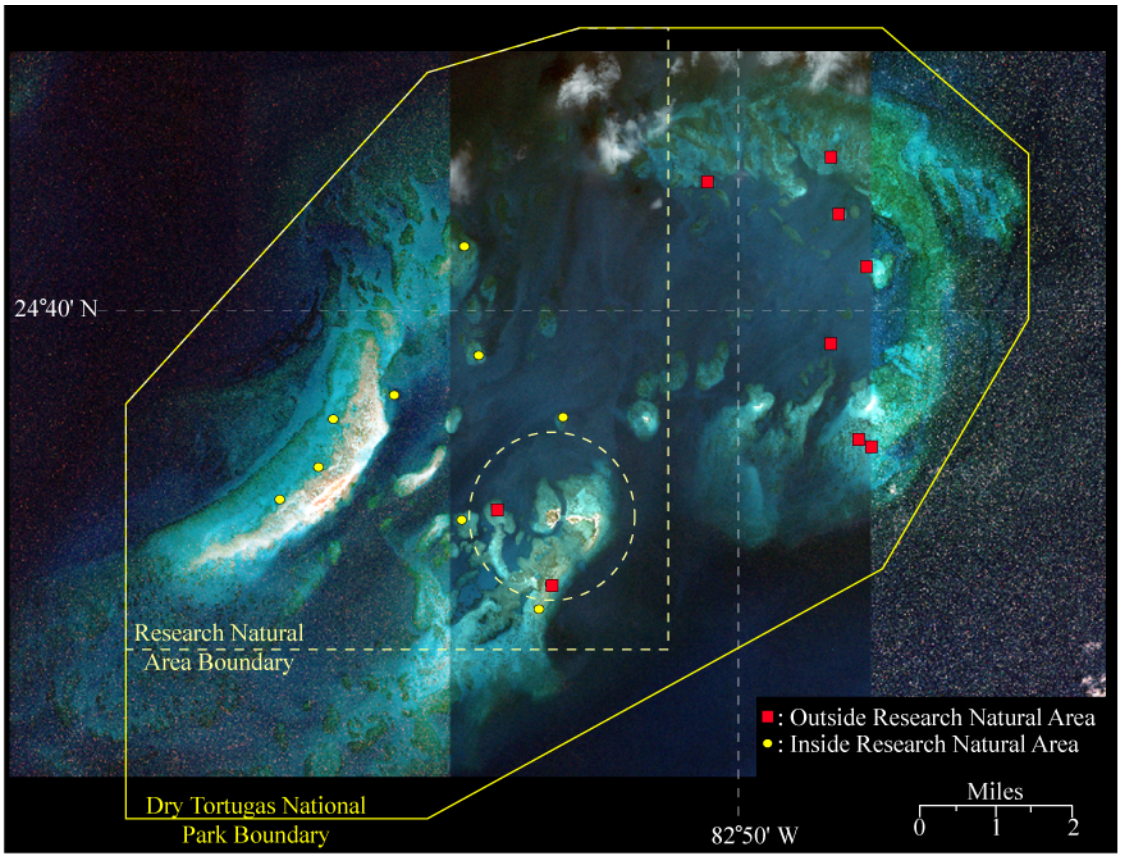

Figure 1: IKONOS satellite mosaic of Dry Tortugas National Park with the locations of 18 randomly selected sites where *in-situ* surveys were conducted October 16 – 20, 2007. The "no-take" Research Natural Area is within the dashed lines in the NW quadrant of the park and does not include the area within the circle.

Material and Methods

We randomly selected 18 sites for surveys, nine inside and nine outside of the RNA (Fig. 1), all within shallow (3- to 6-m depth) low-relief reef and hardbottom habitat. We conducted species-level surveys of macroalgae, scleractinian and gorgonian corals, herbivorous and game fishes, urchins, and substratum composition (e.g., rugosity). Three 15-m transects were laid out radially from each GPS location at bearings of 0°, 120°, and 240°. One Bohnsack-Bannerot visual fish census (7.5-m radius cylinder with stationary observer) was conducted on each transect line (Bohnsack and Bannerot 1986). The benthic community was assessed at n = 4 quadrats (0.0625 m^2 with line demarking 25 equal boxes) per transect by visually estimating percent cover of taxa within the quadrat, and urchins and damselfish were counted in a 2-m-wide belt along each transect line. Rugosity was estimated by draping a chain (3-cm link size) on the substratum underneath each transect line, giving the ratio between contoured and linear distance. Gorgonian and scleractinian diversity at each site was determined by recording all species observed throughout the approximately one-hour-long dive in the proximity of the three transect lines (≈700 m^2 area). The "game fish" category used here included grouper (*Epinephelus*, *Mycteroperca*, *Cephalopholis*, but excluded the small-bodied *Hypoplectrus*), jacks (*Caranx*), snapper (*Lutjanus* and *Ocyurus*), and hogfish (*Lachnolaimus maximus*). Biomass of herbivores was calculated by using length to weight conversions $W=aL^b$, where W = weight in g, L = fork or total length (species dependent) in cm, and a and b are species-specific constants reported by www.fishbase.org. Total length was estimated during visual surveys and then converted to fork length when necessary using regression relationships published on www.fishbase.org.

Results

Our initial assessment of the 18 randomly selected shallow low-relief hardbottom sites revealed that no variables measured were significantly different inside vs. outside of the newly established Research Natural Area (Table 1). *Diadema antillarum* was present and fairly evenly distributed at all 18 sites. Mean densities ranged from 0.01 to 0.54 individuals m^{-2}, with 11 of the 18 sites having densities above 0.10 individuals m^{-2}.

Table 1. Variables measured during *in-situ* surveys October 16 – 20, 2007, in Dry Tortugas National Park. Means, standard errors, and p-values of two-tailed two-sample t-tests are reported for variables comparing sites inside (n = 9) and outside (n = 9) of the "no-take" Research Natural Area established in January 2007. The sites outside are still within the National Park boundaries where there are limited restrictions on resource use, including a ban on spear fishing. "Encrusting invertebrates" includes only *Briareum asbestinum*, *Erythropodium caribaeorum*, and *Palythoa caribaeorum*. [a] = T-test assuming unequal variance using Satterthwait's method as reported by Statistix© 9 software.

Rugosity	Scarid abundance	none	0.28	0.024
Rugosity	Scarid biomass	4^{th}-root	0.49	0.001
Rugosity	*Stegastes* spp.	4^{th}-root	0.29	0.021
Rubble (% cover)	*Diadema antillarum* density	none	0.36	0.009

Percent of the substratum covered by macroalgae was 34% and dominated by the brown algae *Dictyota* spp. *Diadema antillarum* density (Fig. 2A), scleractinian-coral species richness, scarid (parrotfish) abundance (Fig. 2B) and biomass, and *Stegastes* spp. (damselfish) abundance were positively related to rugosity of the substratum (Table 2). *Diadema antillarum* density was also positively related to percentage of the substratum composed of *Acropora cervicornis* rubble, and the amount of variance explained increased (adjusted $R^2 = 0.49$) when both the rugosity and rubble variables were included in a multiple linear regression model. Small (< 1-m-diameter), live colonies of *A. cervicornis* were noted at 12 of the 18 sites.

Discussion

The key question with respect to reef-resource conservation in the Dry Tortugas National Park is "Can we expect to reverse the decline in live coral coverage through the establishment and enforcement of the new no-take RNA?" To have realistic expectations for the RNA efficacy with respect to benthic communities, initial conditions must be assessed and forces that drive coral decline today and in the past must be understood. While there are too few ecological data to determine if the Caribbean-wide mortality of the key herbivore, *Diadema antillarum*, played a role in the replacement of live coral by macroalgae at this location since the early 1980s, it is reasonable to assume that similar changes in algal abundance documented after the die-off in other areas of the Caribbean (Morrison 1988; Carpenter 1990) also occurred in this location. Fishing pressure on herbivorous fishes is certainly a possible confounding factor in comparing sites within the Caribbean region, because scarids and acanthurids are not targeted in the local fisheries throughout the Florida Keys (Harper et al. 2000) whereas they are heavily targeted in places like Jamaica where fishing

pressure is especially intense (Hawkins and Roberts 2004). However, the grand mean of 24% coverage of the benthos by *Dictyota* spp. observed in this study indicates that the herbivorous fish population found in these hardbottom habitats is not sufficient to crop algae to levels documented prior to the 1980s, when benthic algae were thought of as "an inconspicuous component of coral reef environments" (Dahl 1974).

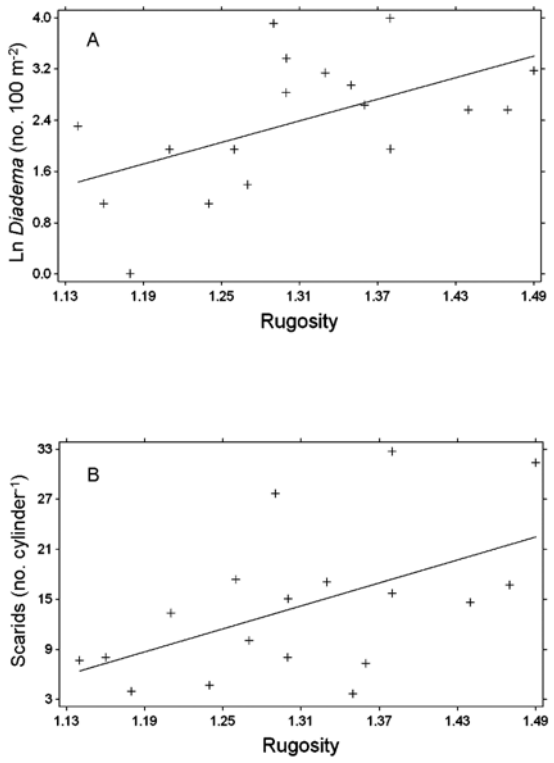

Figure 2: Linear-regression plots of A) *Diadema antillarum* density (Ln transformed data) and B) scarid (parrotfish) abundance (no. cylinder^{-1}) vs. substratum rugosity at 18 sites within Dry Tortugas National Park.

Recent increases in the *Diadema* population (Morrison, pers. comm.) could potentially enhance coral recruitment through the removal of *Dictyota* spp. and other algae from otherwise suitable substratum (Kuffner et al. 2006). Increased abundance of coral recruits in areas where *Diadema* density has rebounded has been documented on Jamaican reefs (Edmunds and Carpenter 2001). The fairly even distribution of low densities of *Diadema* observed in the Dry Tortugas is encouraging, since one of the main factors thought to hinder the recovery of this species is low-fertilization success in remnant populations due to long distances between reproductive individuals, i.e., the "allee" effect (Knowlton 2001).

There is no doubt that increased herbivory could help foster coral recovery. In this vein, the RNA could potentially contribute to restoring a coral-dominated benthic-community structure. However, the removal of stressors that have caused coral mortality in the past is also necessary to reverse reef degradation. As adults, corals may be superior competitors for space compared to most macroalgae, but once coral mortality occurs, the competitive hierarchy changes in favor of selected species of weedy primary producers (McCook et al. 2001; Kuffner and Paul 2004; Kuffner et al. 2006). Coral bleaching and disease are documented causes of recent coral mortality in the Dry Tortugas (Beaver et al. 2005), and since these are global- and regional-scale stressors, respectively, it is not likely that the newly established RNA will be effective in reducing coral mortality; however, managing for resilience could improve coral population recovery rates.

The positive correlation between *D. antillarum* density and percentage of the substratum composed of rubble revealed in this study indicates that testing the hypothesis that *A. cervicornis* rubble acts as nursery habitat for *D. antillarum* would be worthwhile. In an unpublished survey in St. John, USVI, juvenile (< 1 cm-diameter test) *Diadema* were only observed in rubble fields of similar grain size as in this study (Kuffner, unpublished). Chiappone et al. (2001) also noted in June 2000 that the two sites in the Dry Tortugas where they observed the highest densities of *D. antillarum* had large patches of *A. cervicornis* rubble. Little is known about the habitat requirements for recruitment in this species, most likely due to the rarity of finding individuals of < 1-cm-diameter test size and their cryptic juvenile behavior (Bak 1985).

It is too early to speculate whether the RNA will play a constructive role in the future of the benthic community in Dry Tortugas National Park. There is reason for optimism given the recent findings that well-enforced no-take reserves can have restorative effects on trophic functioning (Mumby et al. 2006). Mumby et al. (2006) demonstrated that levels of herbivory increased within a reserve compared to outside, resulting in significant changes to benthic community structure in the form of reduced levels of macroalgae. No-take areas are considered a key tool in managing for reef resilience (Bellwood et al. 2004; Mumby et al. 2007), and there is a growing body of evidence that no-take areas facilitate the recovery of key ecological processes like coral recruitment and herbivory (Hughes et al. 2007). As enforcement of the new management regime gets underway, the Dry Tortugas NP presents a unique case study of no-take area efficacy with minimal underlying problems of land-based pollution found in the adjacent inhabited Florida Keys.

Acknowledgments
Funding for this work was provided through a U.S. Geological Survey State Partnership Program award to IBK, VJP, LJW, and Teresa Turner (U. of the Virgin Islands). VJP and RRW were supported by the Smithsonian Institution Hunterdon Oceanographic endowment (SMSFP contribution #769). The work was performed under National Park Service (NPS) scientific research and collecting permit no. DRTO-2007-SCI-0018. We thank Doug Morrison and PJ Walker of the NPS for scholarly exchange and for processing our permit request, and Clay "Blue" and Janie Douglass of the M/V *Ft. Jefferson* for making our research cruise enjoyable and safe. We also thank Gary Brewer (USGS) for programmatic advice and continued moral and financial support of our on-going work on coral-algal-herbivore interactions. Physiological performance of giant clams (Tridacna spec.) in a recirculation system

A. Kunzmann

Center for Tropical Marine Ecology (ZMT) Bremen, Germany, akunzmann@zmt-bremen.de

Abstract. The importance of auto- and heterotrophy for growth, survival, zooxanthellae development and nutrient uptake of juvenile giant clams *Tridacna maxima* and *T. squamosa* was investigated. In addition experiments on the photosynthesis, metabolism and calcification were performed with specimens of *T. maxima* and *T. derasa* in an intermittent flow-through respiration system. Animals were reared in a recirculation system under different light conditions and different concentrations of nutrients. Both particulate organic (*Tetraselmis* algae) and dissolved inorganic (ammonia and phosphate) food was given. Results show that light intensity and spectra have a significant effect on survival and length or weight increase. Nutrient concentrations only seem to play a role when clams are kept in optimum light conditions. In this case fertilization with NH_4^+ and PO_4^{3-} is more effective than feeding with algae. However, the concentration of zooxanthellae is only moderately increasing with increasing nutrient concentration. Moreover photosynthesis, respiration rates and calcification seem to be linked to light conditions but not to increasing nutrient concentrations. It is concluded that juvenile clams depend more on autotrophy to satisfy nutritional requirements. The uptake of nutrients is limited and needs to be tested with larger clams and a variety of nutrient combinations.

Key words: giant clam, nutrient uptake, growth, photosynthesis, respiration

Introduction

Giant clams are the largest bivalved animals in evolutionary history (Yonge 1975). They are effective filter feeders and at the same time autotrophic due to their symbiosis with zooxanthellae. This gives them a nutritional and growth advantage over normal heterotrophic bivalves. The filter feeding still remains a significant component of their procurement of nutrition (Klumpp et al. 1992). Although Klumpp and Lucas (1994) showed that photosynthates can contribute more daily carbon than actually needed, filter feeding seems necessary to satisfy the requirements for essential amino acids, phosphorous and trace metals (Hawkins and Klumpp 1995).

Although recent research into ecological and physiological background of different stages of the life cycle of clams made commercial aquaculture possible, there is still a high mortality with early stages. While juveniles rely on both heterotrophic and autotrophic feeding, adult clams depend more on available light. Particularly in aquaria the quality of the light plays an important role (Knop 1994) both with regard to light intensity and wavelengths, but negative effects of insufficient light sources are not known in detail.

Clams are raised commercially for human consumption in the Pacific region, sometimes also to replenish natural stocks (Lucas 1994). In addition they are a highly valuable resource for the international aquarium trade. However, losses during transport or during acclimation to aquaria are still high. Even after acclimation periods of several months, spontaneous mass mortalities in aquaria are reported (Knop 1994), most likely linked with water quality in closed recirculation systems. The availability of selected nutrients, particularly for the shell production, plays a key role.

Giant clams are known to prefer locations with gentle water movement, both for the supply of oxygen and nutrients (Knop 1994). When kept in high densities in small aquaria they are able to deplete nitrate and phosphate values considerably. This is why clams can play a potential role for bio-cleaning as additional water treatment module in a closed recirculation system.

Therefore, the importance of auto- and heterotrophy for growth, survival, zooxanthellae development and nutrient uptake of juvenile giant clams was investigated. In addition experiments on photosynthesis, metabolism and calcification under different light and nutrient conditions were performed.

The aims of this study are to:
1) estimate nutrient uptake rates for NH_4^+, PO_4^{3-} and food algae, 2) find optimal light conditions for growth, survival, uptake rates, 3) get an estimation of oxygen

consumption and photosynthetic rates and finally 4) get a first impression of zooxanthellae development and ETR efficiencies.

Material and Methods

From September 2006 to July 2008, 120 juvenile giant clams (*Tridacna maxima*, *T. squamosa* and *T. derasa*; Fig. 1) were reared in a closed recirculation system in ZMT Bremen (500 l volume, 32 PSU salinity, 27 °C temperature, 12 hours light vs. 12 hours dark regime, use of protein skimmer, calcium reactor, nitrate reactor, biofilter, UV units for water treatment). Maintenance conditions and species identification were performed after Lucas (1994) and Knop (1994).

Uptake rate and growth experiments with 30 (5-10 cm) specimens of *T. maxima* and *T. squamosa* were carried out for 21 days under different light conditions (use of HQI 150 W, HQL 125 W, fluorescent lamps 54 W, brand: Aqualine, actinic light) and different concentrations of particulate organic and dissolved inorganic nutrients (microalgae, NH_4^+ and PO_4^{3-}). For experiments (up to four hours exposure) elevated concentrations through spiking were used (5000 cells ml-¹ *Tetraselmis subcordiformis*; 0-150 µM NH_4^+, using ammonium sulphate; 0-10 µM PO_4^{3-} using potassium phosphate). Nutrients were measured with photometer after Koroleff and Grasshoff (1983); cells were counted with a Neubauer chamber. Length (mm) and weight (g) measurements were repeated every 7 days with calliper and electronic scale (Sartorius Germany).

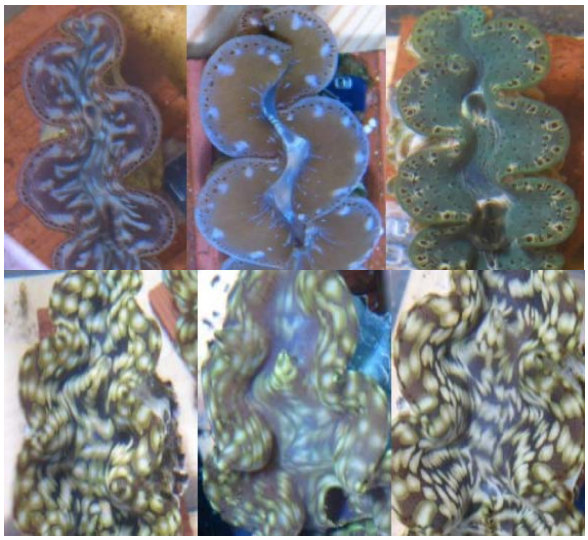

Figure 1: Juveniles of *Tridacna maxima* and *T. squamosa* in recirculation system in ZMT.

Experiments on photosynthesis (PS) and oxygen consumption (OC) were performed with 80 (5-8 cm) specimens of *T. maxima* and ten (10-12 cm) specimens of *T. derasa*.

A separate, PC-controlled intermittent flow respirometer with circular, flat-bottom acrylic respiration chambers of different volumes, according to size of animal, was used (detailed method see Kunzmann et al. 2007). 20 individual clams were measured for 2 hours in light and 2 hours in darkness. WTW 340i oxygen, pH and conductivity sensors were used for measurements of oxygen, salinity and temperature.

For PS measurements 20 individual clams and a PAM 2100 of Waltz (Germany) were used. Light measurements were performed with a Ramses ACC sensor from Trios (Germany), and a LI-250A light meter plus Hamamatsu Photonic multi channel analyser.

Results

Giant clams are capable of fast and efficient NH_4^+ (50 µM) and PO_4^{3-} (2 µM) uptake (Fig. 2, Fig. 3). Within less than 2-3 hours, nutrient concentrations elevated through spiking, are depleted down to normal levels. Only in the case of phosphate uptake in *T. squamosa* a slight delay was observed.

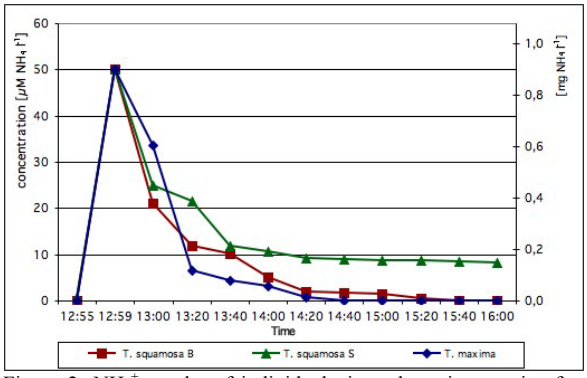

Figure 2: NH_4^+ uptake of individual giant clams in aquaria after spiking with 50 µM NH_4^+, using ammonium sulphate (n=1).

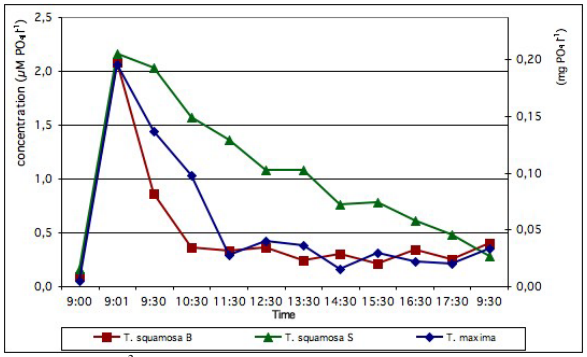

Figure 3: PO_4^{3-} uptake of individual giant clams in aquaria after spiking, using potassium phosphate (n=1).

Consumption of food algae cells reaches up to 7000 $g^{-1}h^{-1}$. The uptake rate was constant for the trial period of 10 hours ($r^2 = 0.9919$, n=10). Light intensity (50 – 350 µE s^{-1} m^{-2}) and spectra have a significant effect on survival and length and weight increase.

With fluorescent light the survival rate went down to 70%, whereas with HQL and HQI lights, survival rates were 90% and 100%, respectively. The condition factor, relating to the overall growth condition of the clams (wet weight/shell length), developed best under HQI light conditions. Fastest length and weight increase of *T. maxima* was achieved with HQI lights (Tab. 1).

Table 1: Growth of T. maxima (n=10) with different light sources, FL= fluorescent lamp.

	HQI	HQL	FL
Length (mm day^{-1})	0.0188 ±0.007	0.007 ± 0.005	0 ±0.003
Weight (g day^{-1})	0.08 ±0.04	0.01 ±0.02	0 ±0.02
Survival rate (%)	100	90	70

Nutrient concentrations only play a role when clams are kept in optimum light conditions. In this case fertilization with NH_4^+ and PO_4^{3-} is more effective for zooxanthellae development or growth than feeding with food algae. However, the concentration of zooxanthellae is only moderately and not significantly increasing with increasing nutrient concentration (from 6 x10^8 g^{-1} wet weight at 0 µM NH_4^+ to 9.5 x10^8 g^{-1} wet weight at 100 µM NH_4^+ under HQI light).

The six HQI light sources provided the same spectrum but differed slightly in intensity (Fig. 4). Resulting ETR rates of different clams were almost identical and display a saturation level of 250 µE $m^{-2}s^{-1}$ at PAR levels of 2500 µq $m^{-2}s^{-1}$ (Fig. 5).

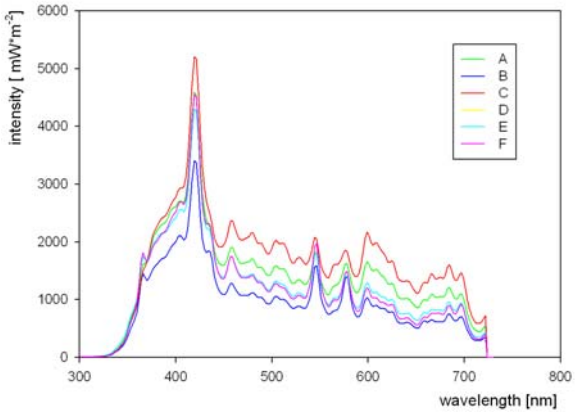

Figure 4: Spectrum comparison of HQI light in six different aquaria.

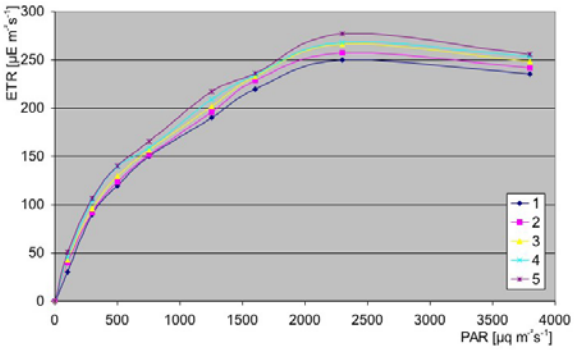

Figure 5: ETR of five different giant clams (*T. maxima*) as a function of PAR.

The oxygen consumption rates (OC) of the same individuals increased slightly over five months, from 0.011 ml O_2 $g^{-1}h^{-1}$ to 0.017 ml O_2 $g^{-1}h^{-1}$. Smaller sized specimens had a higher OC (0.024 ml O_2 $g^{-1}h^{-1}$ to 0.027 ml O_2 $g^{-1}h^{-1}$, Fig. 6).

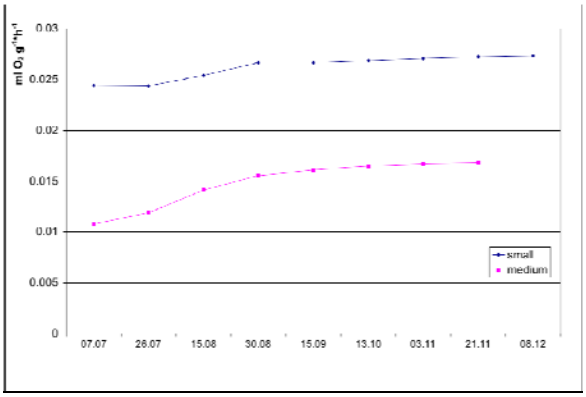

Figure 6: Oxygen consumption rates of the same individuals of *T. maxima* over five months.

Discussion

In this study clam survival is mainly dependent on the lighting conditions; nutrients play a secondary role, at least under experimental conditions and at that age. Only when the clam is kept under optimum conditions clam growth responds positively to the nutrient enrichment. This is in line with other studies (Griffiths and Streamer 1988; Klumpp et al. 1992; Klumpp and Griffiths 1994; Klumpp and Lucas 1994), which have shown that high light intensities may be able to satisfy the basic nutritional needs of clams. But according to Fitt et al. (1993) this strong reliance to zooxanthellae as a source of carbon makes light a limiting factor to growth and survival.

The positive response to nutrients also applies to its symbionts, shown in this study by increased zooxanthellae number, also detected by Braley et al. (1992). The fact that the concentration of zooxanthellae is only moderately and not significantly increasing with increasing nutrient concentration could be due to the short experimental period of 21 days. Ambariyanto and Hoegh-Guldberg (1997) detected a significant effect on zooxanthellae only after three months of nutrient enrichment. The uptake mechanism of zooxanthellae in closed systems might be a problem. The results also show that the symbionts do not have direct access to the nutrients from the water, as proposed by Belda and Yellowlees (1995).

It is not clear yet, why the nutrient uptake, which was also tested under unfavourable light conditions by Hernandez (2006), seems to remain constant, although it is not translated into growth, better survival rates or increase in number of zooxanthellae. Nutrients seem to play a role in the synthesis of the shell, as Schlüter (2005) found changes in shell stability. Marubini and Atkinson (1999) suggest that inorganic nutrients may slow down the calcification.

Similar observations on little effect of nutrient concentrations on clam growth were also made by Ambariyanto and Hoegh-Guldberg (1997) and Sparsis et al. (2001), which is in contrast to results from Hastie et al. (1992), Braley et al. (1992) and Fitt et al. (1993), where a significant contribution of nutrient enrichment to the biomass of the clams was seen. This might be due to the fact that the authors had maintained a continuous flow of nutrients into the water for more than 3 months, while in this study and the above-mentioned studies by Ambariyanto and Hoegh-Guldberg (1997) and Sparsis et al. (2001), spiking only lasted up to 2 to 3 hours a day and this only for a short period of two months. To get more details, additional investigations also on chlorophyll concentrations are planned.

This study has shown that effluents from aquaculture tanks can be supplied to these animals as a source of nutrients, offering possibilities for polyculture. The fact that clams tolerate high concentrations of NO_3^- (pers. observation) would even allow for joint culture with ornamental fish. However, the use of clams for removal of large quantities of nutrients has limits and needs to be investigated with larger specimens and different species. Due to the fact that effluents are always a mixture of several nutrients, the most suitable ratios of N:P need to be tested and adjusted accordingly.

From previous investigations (Lucas 1994) it is known that several specimen being kept in one aquaria, are able to deplete nutrient values considerably. This also applies to calcium, as both calcium and phosphate are needed for the shell production. Growth is slowed down considerably, when either Ca^{2+} or PO_4^{3-} is not available (Schlüter 2005). This needs to be considered when relying entirely on effluents for nutrient supply; aquaculture effluents do not necessarily contain Ca^{2+} in sufficient concentrations.

It is **concluded** that: clams need optimal light conditions, significant nutrient removal is possible but limited, OC rates are size dependent. In future experiments also adult specimens need to be tested.

The aquaculture of giant clams should be increased, both for ornamental and for bio-cleaning purposes. Because of dwindling populations of natural stocks, future work of ZMT will concentrate on improving aquaculture conditions and exploring physiological performance of giant clams under varying environmental conditions, including stress situations and climate change scenarios. Some experiments conducted only with *T. maxima* and *T. derasa* need to be repeated with *T. gigas*, because of its exceptional fast growth.

Future experiments will concentrate on different size ranges and on the reaction to physical, chemical and biological stress, also by modelling effects induced by climate change.

Abstract: Observations of secondary succession of coral reef communities have been carried out at Urasoko Bay, Ishigaki Island, the Ryukyus, southern Japan from 1995 to 2007. Three stations have been permanently established on the outer reef flat, the inner flat, and inshore moat, with four permanent quadrats at each station. At the start of the study in September 1995, all organisms were scraped from the substrate surface. Thereafter, changes in percent cover of hermatypic corals and marine algae have been quantified annually. During the 12-years period, three bleaching events and a typhoon occurred, causing significant disturbance to these sites. Our long-term monitoring results show that recovery to a coral-dominated community (mainly *Acropora* spp.) requires 4-6 years and that transient domination by crustose coralline algae for 2-3 years facilitated coral recovery. It is suggested that crustose coralline algae play a role in construction of firm substrata for settlement and growth of hermatypic corals. The inshore station, which is dominated by rubble, remains nearly in a permanent state of disequilibrium between corals and algae.

Introduction

Recently, the health of coral reefs throughout the world has deteriorated due to various natural and human stresses (Hughes 1994; Wilkinson 1998, 2000, 2002; Bellwood et al. 2004). Coral reefs in the Ryukyus have also been gradually destroyed by pollution, excess sedimentation, bleaching and predation by *Acanthaster planci* (L) as well as by other factors (Nishihira 1987; Fujioka 1999; Yamazato 1999; Ohba et al. 2004, 2006). Restoration of coral reefs is a costly and uncertain endeavor, the techniques of which remain largely experimental (Omori and Fujiwara 2004; Precht 2006; Omori et al. 2008). Results are typically evaluated on an empirical basis with only a marginal understanding of the underlying causes facilitating or inhibiting recovery to a coral-dominated state. Long-term monitoring studies of reefs provide a temporal window on changes in community composition, including natural responses to disturbance. However, such long-term, place-based studies are relatively uncommon. At Urasoko Bay, we have followed secondary succession for 12 years (Fujioka 2002; Fujioka et al. 2006), which includes three bleaching events and a typhoon. Here we summarize the most important findings from this ongoing study with respect to natural resilience and the coral-dominated state in the face of these events.

Materials and Methods

Secondary succession of coral reef communities was monitored at three stations established in Urasoko Bay at Ishigaki Island in the Ryukyu Archipelago. These three stations represented the (A) outer reef flat, (B) inner reef flat, and (C) inshore-side moat (Fig. 1-2). The depth of each station was 0.5-1.5 m and the survey was carried out by SCUBA diving and snorkeling. Four permanent quadrats (1 m x 1 m) were put in place at each station. Subsequently, all organisms were scraped from the substrate surface in all quadrats in September 1995 and again in March 1996. The percent cover, number of species and of colonies of hermatypic corals in each quadrat were measured around in September each year from 1994 to 2007. The percent cover of marine algae in each quadrat was also measured in March 2002 and around September from 2002 to 2005. Percent algal cover from 1994 to 2001 and 2006 to 2007 was evaluated from underwater photographs taken at each quadrat. Percent cover is reported as the average of the four quadrats at each station.

Results and Discussion

In 1994, before the reef surfaces were scraped, tabular *Acropora* dominated all permanent quadrats at Station A with a secondary mix of corymbose and branching *Acropora*. Little algae or other invertebrates were observed (Fig. 3). Various growth forms of *Acropora* formed a mixed assemblage in two of the permanent quadrats at Station B. The rubble derived from branching corals filled the other two quadrats at Station B, and also two quadrats at Station C. Small filamentous, creeping and encrusting algae were observed growing on the rubble. Massive *Porites* dominated the two other quadrats at Station C, as well as a mixture of *Acropora, Pocillopora,* Faviidae and other species.

The percent cover of hermatypic corals at Stations A, B and C increased and reached 43%, 28%, and 24%, respectively, in 1998, three years after the substrate surfaces were scrapped. However, a large-scale coral bleaching event took place in coral reefs worldwide in 1998 (Wilkinson 1998, 2000), which also affected the Ryukyus reefs (Fujioka 1999;

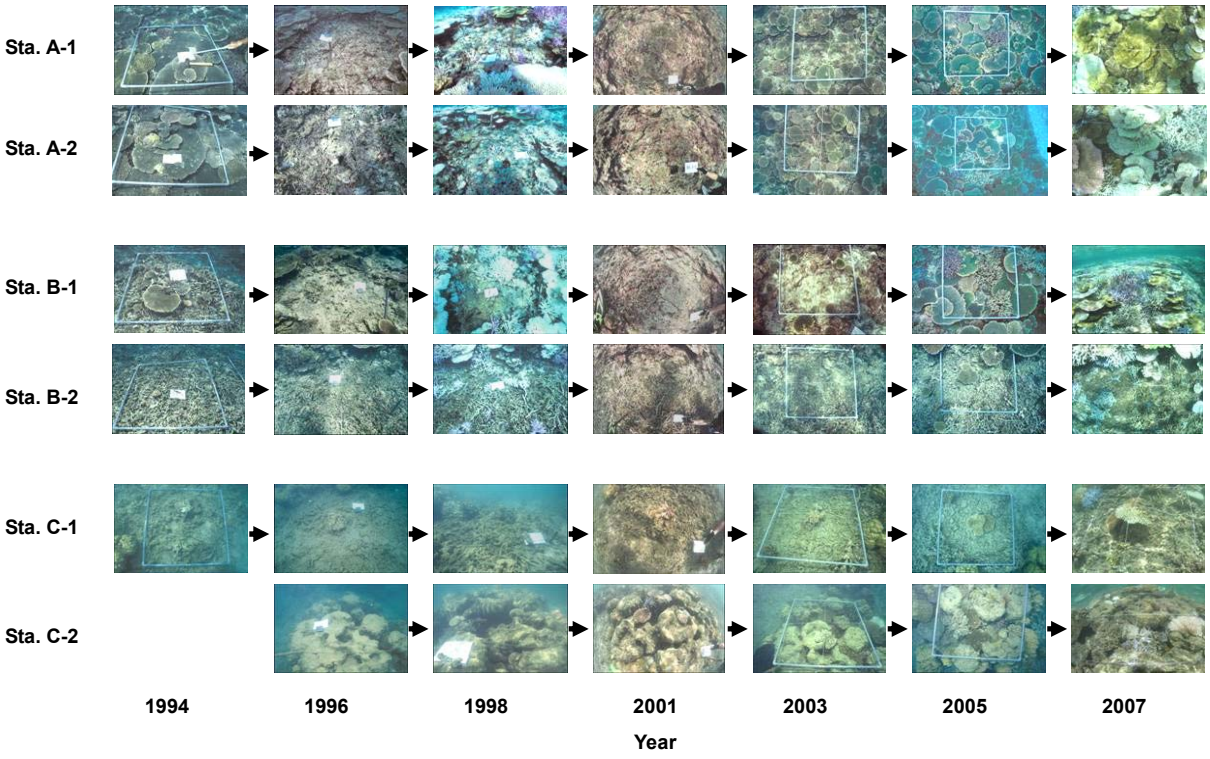

Figure 3: Underwater photographs showing changes in the reef communities in two of the four quadrats at each station in Urasoko Bay. The substrate surfaces in each quadrat were scraped in 1995. A photograph of the Station C-2 in 1994 was not taken.

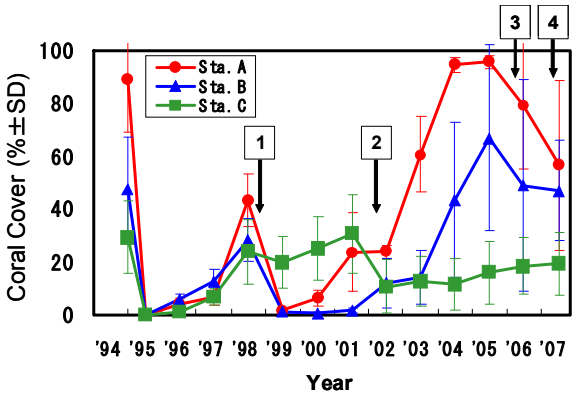

Figure 4: Changes in the percent cover of hermatypic corals at each station in Urasoko Bay from 1994 to 2007. The substrate surfaces in each quadrat were scraped in 1995. Arrows indicate disturbance events: 1. Outbreak of large-scale coral bleaching; 2. Typhoon; 3 and 4. Coral bleaching.

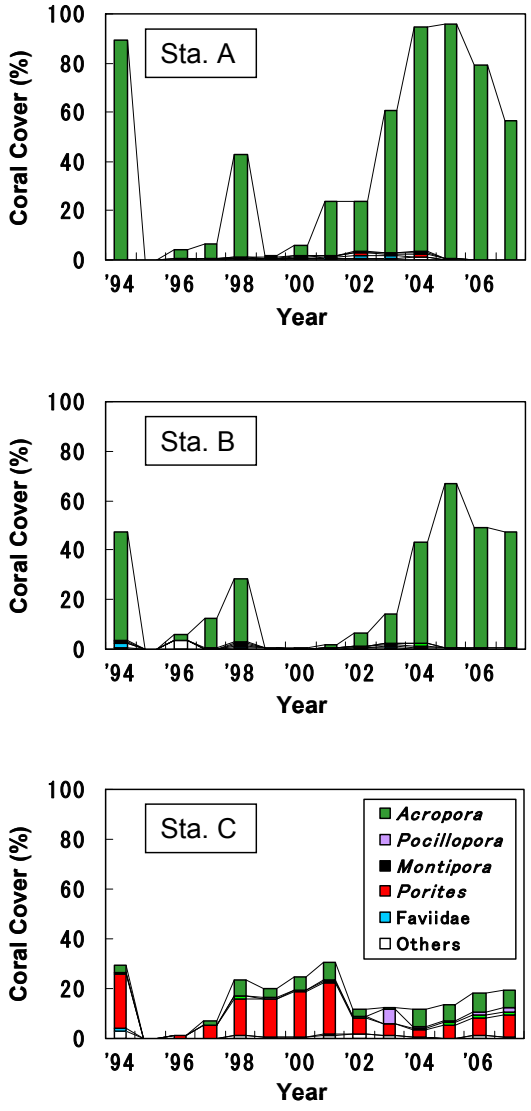

Figure 5: Changes in the percent cover of coral taxa at each station in Urasoko Bay from 1994 to 2007.

Yamazato 1999). During this bleaching event, most of hermatypic corals at Stations A and B died between summer and fall of 1998, although the *Porites* colonies survived at Station C (Fig. 3-4). By 1999, the percent cover of hermatypic corals at Stations A and B was reduced to 1.6% and 0.8%, respectively.

The percent cover of hermatypic corals at Stations A, B, and C increased gradually after the coral bleaching event in 1998 until 2002, when the cover stopped increasing or was again reduced by the damage caused by a large typhoon (No. 16 in 2002). The percent cover of hermatypic corals at Station A rapidly started increasing in 2002 and reached 95% in 2004. The cover at Station B also rapidly increased and reached 67% on average in 2005, with a maximum of 99.5% observed in a quadrat located on the rocks (Fig. 3, Station B-1). The cover at Station C reached a maximum of 31% in 2001, then decreased to only 11% in 2002, followed by a gradual increase to 19% in 2007. Coral bleaching occurred again in the southern Ryukyus in 2006 and in 2007, causing the percent cover of hermatypic

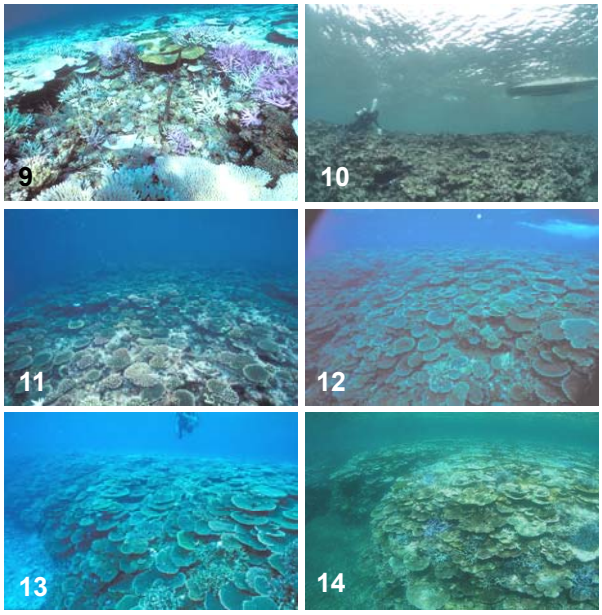
B to decrease to 57% and 47%, respectively, in 2007 (Fig. 4).

The changes in species composition at each station are shown in Fig. 5-6. The sequence of secondary succession was quite different at Station C compared to Stations A and B (Fig. 5). Coral recruits, as well as small filamentous, creeping, encrusting algae and crustose coralline algae immigrated and began to grow at Stations A and B in 1996, a year after the substrate surface had been scrapped. This recovery was highlighted by the resettlement of *Acropora* recruits. *Acropora* basal discoid parts were observed from a half to one year after the settlement. These recruits began to grow into an upright morphology from the center of their basal sections in 1997 and 2001. The growth rate of the upright part of *Acropora* was rapid, with an increase in the diameter of the colonies of 30-50 cm by 2005. When the secondary succession on the rocks at Stations A and B reached a climax (i.e., coral domination), the species composition and cover of the hermatypic coral community were similar to those of the original community in 1994. At Station C, *Acropora* recruits were much fewer than those in Stations A and B,



Figures 9-14: Underwater photographs showing an alternation of damaged and recovered coral reefs at Station A in Urasoko Bay from 1998 to 2007. 9. Large-scale coral bleaching in September of 1998. 10. Dead coral community in September of 2001. 11. Recovered coral community in October of 2003. 12. Almost recovered coral community in September of 2004. 13. Completely recovered coral community in September of 2005. 14. Coral bleaching occurred again in August of 2007.

whereas the recruits of many kinds of *Porites, Pocillopora, Montipora,* Faviidae and other genera were present on the rocks (Fig. 5). In Particular, massive *Porites* dominated from 1997 to 2002. The species composition and cover of hermatypic corals at Station C in 2001 were similar to those of the original community in 1994.

Green algae such as *Halimeda hederacea*, brown algae such as *Dictyota friabilis* and *Lobophora variegata*, and red algae such as *Gelidium pusillum, Hydrolithon onkodes, Mesophyllum erubescens* and crustose coralline algae (CCA) temporarily appeared and grew luxuriantly during 1995 to 1997 and during 1999 to 2003, before the hermatypic coral community became dominant at Stations A and B (Fig. 6-8). Crustose coralline algae kept growing on the substrate at all stations. In particular, a thick crustose coralline alga, *Mesophyllum erubescens* (Fig. 8), had dominated on the rocks at Stations A and B from 1999 to 2002. The percent cover of crustose coralline algae gradually decreased with the growth of corals (Fig. 6). Previous research highlighted the importance of crustose coralline

algae as coral settlement inducers (Morse et al. 1996). In addition, coralline algae may construct the firm substrates for settlement and growth of hermatypic corals by covering the surface like a cement, and therefore may possibly inhibit the perforation of many micro-organisms which damage the framework of substrates. Similarly, it is supposed that, in the Ryukyus, crustose coralline algae may play an important role in facilitating the settlement of coral recruits and acting as an important member of the reef-builder functional group.

On the rocks around the outer reef flat in Urasoko Bay, two sequences of secondary succession are recognized. In the first case, the hermatypic coral community recovered directly between 1995 and 1998. In the second case, the coral community recovered after a phase of algal overgrowth that lasted for 2-3 years between 1998 and 2005. The climax of the secondary succession, where *Acropora* community is formed, seems to be reached 4-6 years after the start of the succession, as long as the coral reefs remain in good health and are not subjected to large disturbance such as coral bleaching, sedimentation, typhoons or other bad factors (Fig. 9-14). In contrast, the coral community found on the rubble and rocks located at the inshore-side of Urasoko Bay seems to take longer to reach the climax of the secondary succession. It is considered that the recruitment of coral planulae may be reduced in the moat, and that the loose rubble is an unstable substrate which limits coral planulae settlement. The sequence and speed of the secondary succession were influenced by substrate stability and the various sources of disturbance that characterized each habitat.

In conclusion, long-term monitoring studies provide insights into the cause of successional differences in response to disturbances that delay or enhance coral domination as an alternate stable state. For fast growing corals such as *Acropora*, recovery from catastrophic events may be ultimately impossible, but as shown here, even with periodic bleaching events and storms, recovery is possible in a timeframe of a few years. Given that coral bleaching and storms are ongoing processes, it remains paramount that anthropogenic impacts such as pollution and dredging be curtailed.

Abstract. The southeast Florida reef system faces a number of stress factors, among which ship groundings are one of the most physically damaging. Portions of the Florida reef tract located near Port Everglades, Broward County, Florida, USA have been damaged by ship groundings. In 2004, physical damage of more than 30,000 m^2 was caused by the groundings of two large cargo ships, the MV *Eastwind* and MV *Federal Pescadores.* The present study was designed to measure differences of scleractinian coral recruitment patterns (recruit diversity and richness) and rates to these injured sites in comparison to undamaged reef sites. Coral recruitment rates were measured on unglazed ceramic tiles deployed for a period of one year from February 2007 to February 2008 at five different locations: three control sites (including a high coral cover site), and the two ship grounding sites. Morphology and genetic markers including CO1 and cytb were used to identify the coral recruits. A whole genome amplification kit (REPLI-g, Qiagen) was used to obtain sufficient amounts of DNA. Results revealed low recruitment rates (0.5-2.7 recruits m^{-2} yr^{-1}) to the studied sites, suggesting a low potential for recovery of the damaged areas.

Key words: reef groundings, coral recruitment, genetic markers

Introduction

Coral reefs around the world have been affected by anthropogenic changes in the environment, resulting in a general pattern of decline worldwide. A substantial number of these stressors also affect the Florida coral reef system, and ship groundings have been found to be particularly destructive (Jaap 2000; Collier et al. 2008). Reef areas located near Port Everglades, Broward County, FL have been severely impacted due to the location of a portion of the port anchorage area between two major reef tracts: the middle and outer reefs. Navigational error and inclement weather have resulted in a number of ship groundings and anchor damage events. From 1993 to 2006, there were 11 groundings and 6 anchor drag cases, resulting in more than 40,000 m^2 of coral reef injury in the vicinity of Port Everglades (Collier et al 2007, Banks et al. 2008). In 2004 the most severe impacts were groundings of two cargo ships: the MV *Eastwind* in March and the MV *Federal Pescadores* in October, which destroyed more than 30,000 m^2 of reef (Melendez 2004; Flesher 2004).

Coral recruitment is a vital step in the natural recovery process of injured reefs. Thus, understanding the process of coral recruitment to these areas is essential in evaluating the ability of reefs to recover (Smith 1992; Tougas and Porter 2002; Glassom et al. 2004). At 26°N latitude, Broward County is near the northern range limit for many scleractinian coral species, which may lead to an assumption of low recruitment rates and thus slow recovery. The present study was designed to estimate scleractinian coral recruitment rates and patterns (species diversity and richness) to damaged reef sites three years after the initial impacts of the two cargo ships MV *Eastwind* and MV *Federal Pescadores*. It also aimed to determine differences in coral recruitment patterns and/or rates between undamaged parts of the reef and sites which were destroyed by ship groundings. This study has provided the first estimation of scleractinian coral recruitment rates on reef sites off the coast of Broward County, FL.

One of the challenges of coral recruitment studies is properly identifying coral recruits. Previous researchers have typically been able to morphologically categorize recruits only to the family level because of the small size (< 1 to several mm) of many recruits (Baggett and Bright 1985; Harriott 1992; Tougas and Porter 2002). However, genetic markers have been used to overcome the difficulty in morphological identification of early life stages (gametes, larvae, juveniles) of a number of marine

organisms (Neigel et al. 2007). The cytochrome *c* oxidase subunit 1 (CO1) mitochondrial gene has been used to identify coral recruits settled on ceramic tiles (Shearer and Coffroth 2006) and revealed a great advantage in the ability to identify recruits as small as 1 to 2 mm in diameter. In this study, genetic markers including CO1 and cytochrome b (cytb) genes were used to supplement the morphological identification of coral recruits to a lower taxonomic level.

Material and Methods

Coral recruitment rates were measured on unglazed ceramic tiles deployed off the coast of Broward County for a period of one year from February 2007 to February 2008. A total of 480 ceramic plates (8 per array, Fig. 1) were deployed, resulting in 22.3 m^2 of settling area under study.

Figure 1. Settlement plate array design. Twelve arrays deployed to each of 5 sites for a period of one year.

The settlement plate arrays were deployed at five sites (12 arrays per site): three control sites (including one high coral cover site) and two ship grounding sites (*Eastwind* and *Federal Pescadores*) (Table 1). After 12 months on the reef, the plates were collected, transported in coolers and frozen (-20° C) until microscopic and genetic examination. The tiles were examined for coral recruits under a dissecting microscope at 12X magnification, and the recruits found were identified by morphological characteristics to family or genus level according to the identification keys in Budd et al. (2006) and Smith (1948).

Each scleractinian spat was then scraped with a razor blade and preserved in a saturated sodium chloride 2.5M EDTA, 20% dimethyl sulfoxide (DMSO) buffer for genetic analysis. DNA extraction was completed with a DNeasy isolation kit (Qiagen). For samples with low concentration of extracted DNA, a whole genomic DNA was amplified with REPLI-g kit (Qiagen). The CO1 was amplified by the polymerase chain reaction (PCR) using coral–specific primers and cycling conditions suggested by Fukami et al. (2004).

The cytb and ITS genes were amplified using newly designed primers; CYTBF: 5'-GGGTGTTT TTTGTCBATGCATTAT-3', CYTBR: 5'CCCAATT TATTTGGTATCGAACGCA-3', ITSF:5'GGGGAC AGAGMGTCGGAT-3', ITSR:5'-TCCGGGKAGAA AGTGCTTCT-3'.

Table 1. Location of five reef sites in Broward County, FL; CS1 = control site one, CS2 = control site two, HC1 = high coral cover site, EW = *Eastwind* and FP = *Federal Pescadores*

SITE	LATITUDE	LONGITUDE	DEPTH (m)	REEF TYPE
CS1	26°09.625'N	80°05.306'W	6.5-7.5	INNER
CS2	26°10.073'N	80°05.265'W	6.5-7.5	INNER
HC1	26°08.857'N	80°05.763'W	6.5-7.5	RIDGE COMPLEX
EW	26°07.042'N	80°05.549'W	9.0-10.0	INNER
FP	26°06.747'N	80°05.504'W	11.5-12.5	INNER

The PCR protocol for the above primers was 35 cycles at 94°C for 45s, 50°C for 45s, and 72°C for 90s. Following the work of Shearer and Coffroth (2004), the restriction fragment length polymorphism (RFLP) patterns of the CO1 gene were used for partial identification of the recruits. First, virtual RFLP patterns for major scleractinian coral species were created with a Web-based nucleic acid analysis tool (http://workbench.sdsc.edu/) using CO1 sequences available in GenBank. The CO1 RFLP patterns of recruits were created by Taq1 restriction digestion of the amplified gene and then compared to the virtual patterns of known species. Because of the low interspecific variation in CO1 gene sequences among scleractinian corals (especially in the family Faviidae), the CO1 RFLP was useful to differentiate only two of the coral species from the genus *Porites*. CO1 and cytb genes acquired from coral recruits that were not distinguished by RFLP patterns were sequenced and blasted to find the best possible match in GenBank. In case of low concentration or low purity of the PCR results, products were cloned with TOPO TA Cloning kit (Invitrogen). The final identification was made based on the combined morphological analysis RFLP patterns and BLASTN queries (www.ncbi.nlm.nih.gov/BLASTN).

Results

A total of 33 coral spat were found on 478 tiles (two tiles were lost). The overall recruitment rate was estimated to be 1.5 recruits m^{-2} yr^{-1}, ranging from 0.5 recruits m^{-2} yr^{-1} at the *Federal Pescadores* ship grounding site to 2.7 recruits m^{-2} yr^{-1} at both the control site 1 and high coral cover site (Fig. 2). A one-way analysis of variance showed no significant difference among recruitment rates from the five studied sites, likely due to a small sample size. The lowest number of recruits settled on tiles located at the *Federal Pescadores* ship grounding site (2 recruits) and the highest number of recruits were found on tiles from control site 1 (11 recruits) and the high coral cover site (10 recruits) (Table 2).

The identification process of scleractinian coral recruits using genetic markers was successful for all but one sample. The small size of the recruits, which in several cases were less than 1 mm in diameter, resulted in extraction of very small amounts of DNA. Another challenge was related to recruit DNA contamination with zooxanthellae DNA. The easiest markers to be obtained from this poor quality DNA were CO1 and cytb mitochondrial genes.

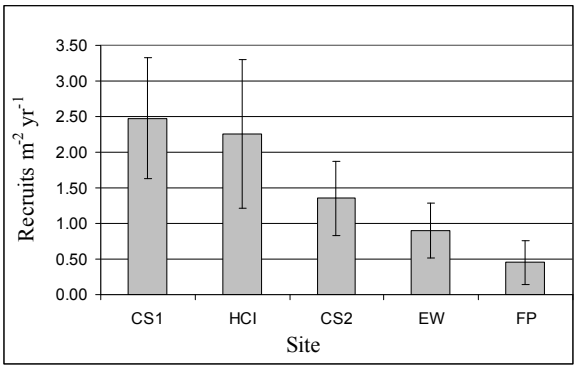

Figure 2. Scleractinian coral recruitment rates found on settlement tiles located on five reef sites in Broward County, FL. Mean values are calculated per array (n=12) with error bars indicating standard errors. CS1 = control site one, CS2 = control site two, HC1 = high coral cover site, EW = *Eastwind* and FP = *Federal Pescadores*.

Amplification of nuclear genes such as ITS turned out to be more challenging and was only successful for a few of the largest recruits. One method of improving results was to amplify the whole genome using a REPLI-g kit from Qiagen which allowed an increase in the concentration of DNA template (Table 3). This technique showed potential to be a useful tool when very small samples such as gametes, larvae and other early life stages are involved, since target genes could still be amplified.

Table 2. Comparison of scleractinian coral recruitment rates and patterns among five reef sites. CS1 = control site 1, CS2 = control site 2, HC1 = high coral cover site, EW = Eastwind grounding site, and FP = Federal Pescadores grounding site.

FP	2	1	2	0.00	0.54

The restriction digestion performed on the CO1 gene (total 742 bp) with Taq1 restriction enzyme resulted in 4 different RFLP patterns (Fig, 3). Patterns designated with letters B (2 fragments: 446, 296 bp) and C (3 fragments: 330, 298, 116 bp) were species-specific for *Porites astreoides* and *Porites porites*, respectively. Patterns A (2 fragments: 613, 129 bp) and D (3 fragments: 374, 296, 72 bp) were characteristic of multiple species, so recruits with these two patterns were chosen for better resolution via CO1 and cytb sequencing analysis.

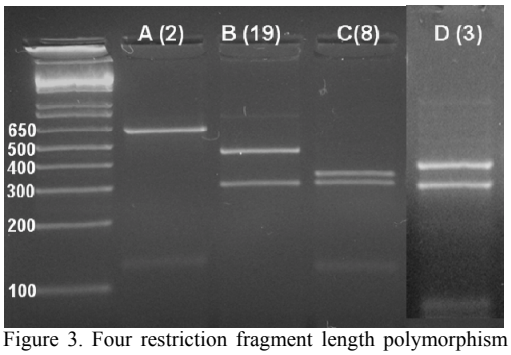

Figure 3. Four restriction fragment length polymorphism patterns named A, B, C, and D created from the CO1 gene amplified from scleractinian coral recruit DNA samples and digested with Taq1 restriction enzyme. The number in parenthesis indicates the number of times the pattern was found.

Table 3. DNA concentrations extracted from coral recruits, and DNA concentrations of the same samples after whole genome amplification determined by Nanodrop ™

CS212	3.59	250.94
CS146	3.86	333.86
CS261	6.50	246.38
HC126	10.17	270.72

There were a total of four coral recruit genera found on the tiles. The most dominant coral species recruiting to all five sites were *Porites astreoides* and *Porites porites* comprising 82% of all the recruits. Twelve percent of the coral recruits consisted of species from the genus *Agaricia,* and the remaining 6% (two recruits) were *Montastraea cavernosa* and *Colpophyllia natans*. The last two mentioned were the only two recruits of reef framework-building corals. These recruits were found on tiles from the high coral cover site which had the highest diversity (all four genera represented) of all the studied sites (Table 2).

Discussion

Overall coral recruitment rates and patterns

The present study on reef sites off Broward County, FL demonstrated extremely low recruitment rates, between 0.5 to 2.7 recruits m^{-2}. The low recruitment rates to these reefs were not surprising due to their location on the northern extent of the Florida reef tract which is characterized by relatively low coral cover.

In Florida and the Caribbean coral recruitment rates have been declining most likely as a consequence of the overall decline of coral population densities (Porter et al. 1988; Jaap et al. 2000; Santavy et al. 2005, Hughes and Tanner, 2000). Through meta-analysis, Gardner et al. (2003) have estimated an 80% reduction in coral cover in three decades between 1977 and the present for the entire Caribbean basin. Extensive coral cover losses certainly have led to a decrease in coral breeding stocks, thus resulting in reduced larval supply and low recruitment rates.

The most dominant coral species recruiting to the studied reef sites were *Porites astreoides* and *Porites porites* which constituted 82% of all the recruits. The next dominant species were from the genus *Agaricia* (12%). The trend of dominant recruitment of agariciid and poritiid corals has been documented in several other studies of coral recruitment on Florida and Caribbean reefs (Bak and Engel 1979; Rogers et al. 1984; Smith 1997; Hughes and Tanner 2000; Tougas and Porter 2002; Shearer and Coffroth 2006). The recruitment patterns found in previous studies have been explained by either: a) the existence of two different life histories exhibited by scleractinian corals (broadcasting vs. brooding) (Bak and Engel 1979) or b) the Allee Effect of low population densities (Knowlton 2001).

The first theory states that coral species which are massive, long-lived, reef frame-builders and usually broadcast spawn their gametes into the water have low recruitment rates and are represented by a low number of juvenile colonies. The low recruitment rate, however, is then compensated by lower post-settlement mortality and good competing and surviving abilities (Bak and Engel 1979; Smith 1992 1997; Hughes and Tanner 2000). In contrast, small-sized, short-lived species that brood their larvae exhibit higher recruitment rates but also suffer from higher post-settlement mortality rates. The adult community structure with the dominance of massive broadcast spawning species like *Montastraea* spp. and *Diploria* spp. over small, brooding species such as *Porites* spp, *Agaricia* spp. and *Favia* spp. is thus the result of the two opposite life strategies.

The Allee Effect mostly affects broadcasting species which generally do not self-fertilize, so high gamete densities are necessary for successful fertilization and reproduction (Knowlton 2001). Low population densities of these species lead to asynchronous spawning events (limited hormonal regulation), low gamete densities and consequently to the increase in reproductive failure. Brooding species can self-fertilize, and their larvae can settle within hours to days of release. Therefore, they are more likely to persist through periods of low densities. The Allee Effect creates a major shift in the structure of coral adult communities from those dominated by framework builders toward those dominated by non-framework opportunists such as *Porites*. Both the differing life history strategies and the Allee Effect could be the cause of *Porites* dominated recruitment patterns in Broward County, FL.

Recovery process in terms of recruitment rates on ship grounding sites

Ship groundings on coral reefs cause not only serious damage to the reef builders, but also result in a loss of habitat for other animals, consequently leading to barren areas. The problem, however, may be further intensified by other stress factors (climate change, disease, pollution, eutrophication and sedimentation) which decrease coral population size, impact the size of coral breeding stocks, larval supply and recruitment rates, and increase post-settlement mortality rates, consequently resulting in unlikely recovery of the damaged sites.

The present coral recruitment data showed that a small number of coral recruits settle on tiles located on the studied ship grounding sites suggesting a very slow recovery process and unlikely recovery success. Additional studies of coral recruitment involving artificial and natural substrates are required to confirm the low recovery potential of these and other physically damaged sites in Broward County, FL.

Genetic identification

This study demonstrated that genetic markers help overcome the difficulty in morphological identification of early life stages such as small juvenile coral recruits. We confirmed the usefulness of the CO1 gene in partial species or family level identification of scleractinian coral recruits as it was developed by Shearer and Coffroth (2006). RFLP analyses of the CO1 gene allowed differentiation between at least two species in the coral genus *Porites*. The low nucleotide polymorphism in CO1 was, however, insufficient to distinguish some closely related coral species (Shearer and Coffroth 2007; Neigel 2007), but a better genetic marker has not yet been developed for this purpose.

This study tested other genetic markers including cytochrome b and internal transcribed spacer region (ITS) for species identification of corals in the early developmental stage. Coral-specific primers were designed and tested in order to avoid amplification of zooxanthellae genes. Nuclear markers were difficult to amplify from the small amounts of DNA. Similar to the CO1 gene, the cytb gene showed limited genetic variation, which limits the number of species specific RFLP patterns. However, the combination of obtaining both gene sequences allowed better species

identification, which could be improved with more markers.

Underestimated Eroder among Reef Fishes – Experimental Comparison between *Ctenochaetus striatus* and *Acanthurus nigrofuscus* (Acanthuridae)

H. Schuhmacher[1], R. Krone[2], P. van Treeck[1]

[1]Department of Hydrobiology, University Duisburg-Essen, 45117 Essen, Germany
[2]Division Marine Animal Ecology, Alfred Wegener Institute for Polar and Marine Research, 27568 Bremerhaven, Germany

Abstract. The acanthurid fish species *Ctenochaetus striatus* and *Acanthurus nigrofuscus* are common detritivore browsers. Less is known about their erosion potential. We offered coral limestone for grazing in aquarium experiments and recorded the feeding behaviour by video. *C. striatus* produced 15 times more calcareous sediments compared to *A. nigrofuscus* despite of a 5 times higher biting rate of *A. nigrofuscus*. Whereas *A. nigrofuscus* performed careful picking bites only, *C. striatus* showed soft sweeping of the surface alternating with chafing the substrate with grasping bites. Hereby a special palate structure (bow of hard knobs in the upper jaw) is engaged which allows to rasp the reef substrate. The measured eroded masses per bite and the number of bites per individual were related to the population densities of the two species on three reef crests in the Northern Red Sea. Based on these extrapolations, *A. nigrofuscus* attains maximum erosion rates of 2.6 g m^{-2} yr^{-1} and may therefore not be regarded as a relevant bioeroder, but *C. striatus* achieves erosion rates of up to 70.0 g m^{-2} yr^{-1} which is in the same order as that of the co-occuring sea urchin *Diadema setosum.*

Key words: Detritivore acanthurids, jaw morphology, bioerosion, Red Sea

Introduction

Coral limestone plates which were set up for colonization experiments at Aqaba (Jordan, Northern Red Sea) were found to be eroded after two years by up to 6.12 mm (v.Treeck et al. 1996). The experimental set-up excluded bioeroding sea urchins, but not grazing fish. Surgeonfishes and parrotfishes are the principal grazing groups with many fishes in the latter family capable of scraping and excavating coral limestone (Glynn 1997). In situ video recordings and observations showed that the plates were most frequently grazed by the acanthurid fish *Ctenochaetus striatus* (Quoy and Gaimard 1825) and *Acanthurus nigrofuscus* (Forsskal 1775). Scaridae, however, were rare. Hence, the feeding behaviour of the two species which are known as detritus feeders (Randall and Clements 2001) was investigated in aquarium experiments with supplementary observations in three reefs in the Northern Red Sea.

Trials to run experiments close to the reef in the laboratories of the Ras Mohamed National Park (southern tip of Sinai-Peninsula) could not be sufficiently standardized, since we were not allowed to catch the wanted specimens, but depended on the supply of healthy fishes by Bedouin fishermen. In addition we arranged an experimental set-up in the university aquarium plant in Essen. These data, albeit obtained from a necessarily limited sample size, are presented here and discussed in conjunction with the specific jaw morphology of the two fish species.

Material and Methods

Aquarium trials were run at the University of Duisburg-Essen in spring 2005 with fish obtained from the aquarium trade.Two subadult individuals (8-9 cm TL) of each species were at our disposal. *Favia* plates from the same stock as had been used in the above mentioned experiments at Aqaba were immersed in seawater taken from an aquarium accommodating "living rocks" and invertebrates from the Red Sea, until being covered with a veneer of diatoms, green and bluegreen algae; then they were offered to the individual fish. These had been kept without food for one day to empty the intestinal tract. The browsing activities were recorded by video. After 7-8 hours the plates were removed. The fish, however, remained in the tank for another 12 hours without food. Then all loose particles (i.e. predominantly faeces, not ingested but removed limestone particles, and material generated by handling) were sucked off and collected in 50 µm gauze. These sediments were analyzed for their dry weight carbonate content.

As control, a coral slab of the same size was similarily handled in an aquarium – without fish. To prevent coprophagy during the time when the fish's gastrointestinal tract was emptied a net was installed a few cm above the bottom.

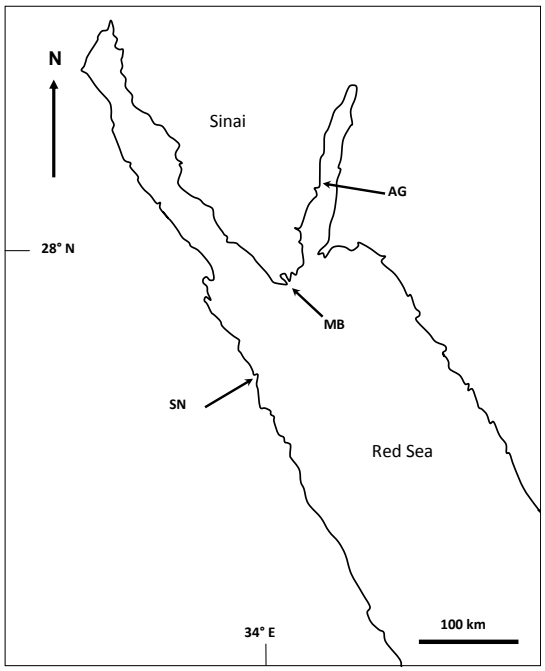

Figure 1: Map of study sites, see text for details.

Field observations were performed by extensive snorkelling on three reefs at different seasons: 1. Abu Galum (AG), 2. Marsa Bareika (MB), and 3. Sharm el Naga (SN, see Fig. 1). Individual fish were observed for several hours at different times of the day counting those bites which clearly occured on hard substrate. Bites on sponges, fleshy algae, and sand covered substrate were ignored. Therefore, the recorded bites per day represent minimum values. The abundance of the acanthurid fish was recorded at the three sites by counting all individuals within 50x5 m transects (3 replicates), placed on the reef crests with a distance of 2.5 m to the edge (English et al. 1997).

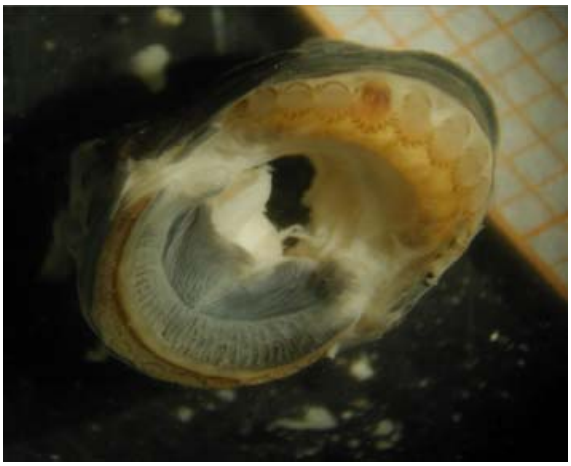

Figure 2: Opened mouth of *A.nigrofuscus*; upper jaw with millimetre grid in background.

Results

Corresponding to the aquarium experiments of Purcell and Bellwood (1993) we found two different feeding techniques.

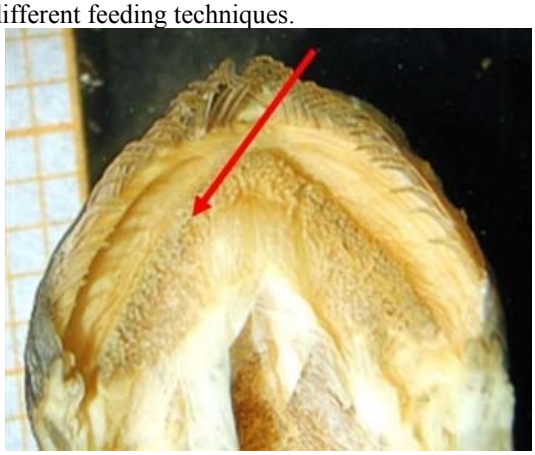

Figure 3: Upper jaw (top) and lower jaw (bottom) of *C. striatus*; arrow points to the knobby structure behind the bristle-like teeth.

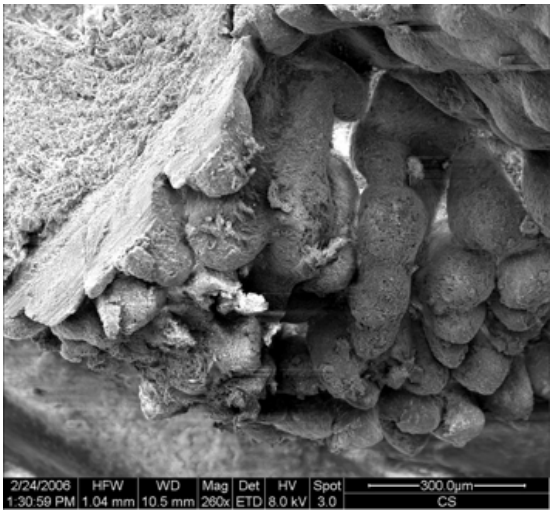

Figure 4: SEM picture of a section of the hard palate structure pointed to in Fig.3.

A.. nigrofuscus grazes with a minimal contact to the substrate. It feeds using quick punctual bites. *C. striatus* feeds opening its mouth up to an angle of 180° sweeping the substrate with its jaw bristles; in addition, forceful grasping bites at which the whole body is shaking and exerting thrust were observed.

Table 1 provides data on number of bites and removed carbonate masses. Although *A. nigrofuscus* showed a five times higher bite rate, fifteen times more loose calcareous matter was found to be produced by *C.striatus* inside the aquarium. Hence, an erosion rate of 0.09 mg per bite results for *C. striatus* compared to 0.001 mg/bite for *A. nigrofuscus*.

On all three reef sites both acanthurid species were very common and much more abundant than scarids (details of the surveys are omitted here).

The pooled data of bites per day of a single individual are 13679 (SD ± 2177) for *C. striatus* and 22220 (SD ± 5092) for *A. nigrofuscus*. Combining the experimentally obtained data of removed carbonate material per bite and observed number of bites on the reef per day results in the following hypothetical approximations of erosional efficiency: 449 g/ind.yr for *C. striatus* versus 6 g/ind.yr for *A. nigrofuscus.*

Table 1 Number of bites and amount of produced sediment [mg] per experimental run

A. nigrofuscus						
Individual A				Individual B		
Bites	mg	mg/bite		Bites	mg	mg/bite
27751	37.81	0.0014		13070	5.08	0.0004
22367	32.12	0.0014		6368	7.93	0.0013
C. striatus						
Individual A				Individual B		
Bites	mg	mg/bite		Bites	mg	mg/bite
5063	543.10	0.1073		1524	125.24	0.0822
3788	362.59	0.0957		3181	230.26	0.072

Discussion

The experiments resulted in a clear answer to the initial question which of the two acanthurids was responsible for the erosion of the *Favia* plates. A look at the mouthparts of the two species is helpful to understand the significant difference in the capability to remove carbonate substrate. The spatulate teeth of *A. nigrofuscus* are arranged in bundles (Fig 2) – well adapted to collect fine detrital material and algae. *C. striatus* is equipped with bristle-like teeth – well suited to sweep the bottom and to take in loose material (Fig. 3). In addition, there is a bow of hard knobs in the upper jaw (arrow in Fig. 3, SEM photo, Fig 4). This special palate structure is engaged to abrade hard bottom (Krone et al. 2006). This until recently overlooked morphological detail qualifies *C. striatus* as bioeroder – in addition to its affiliation to the guild of detritus feeders. The annual erosion impact of *C. striatus* is comparable to that of the sea urchin *Diadema setosum* in the Gulf of Aqaba which are eroding carbonate masses varying between 1023g/ind. (Kroll 1995) and 113g/ind. (Mokady et al. 1996).

On the basis of our estimates of abundance on some reefs *C. striatus* can achieve erosion rates of up to 70.0 g m^{-2} yr^{-1} which again reaches the same order of magnitude as that of the co-occuring sea urchin *Diadema setosum*. *A. nigrofuscus*, however, attains maximum erosion rates of 2.6 g m^{-2} yr^{-1} and may therefore not be regarded as a significant bioeroder.

The presented data and extrapolations are definitely conservative, since they were obtained from subadult fishes feeding on an especially hard substrate not yet weakened by endolithic borers (dried *Favia* plates were used to have standardized conditions with regard to the experiments mentioned in the introduction). Supplementary experiments run in the wet lab of the Ras Mohamed Park with natural reef substrate yielded five times higher excavation rates (unpub. data).

On the basis of the presented pilot study it might be fruitful to investigate the ecological functions of *C. striatus* within the sediment regimes of Indo-West-Pacific reefs in more detail.

Differential effect of early post-settlement processes on the abundance of two concurrently settling coral reef fishes

H. Vallès[1], D. L. Kramer[1], W. Hunte[2]

1) Department of Biology, McGill University, 1205 Dr. Penfield Avenue, Montreal, Quebec, H3A 1B1, CANADA
2) Department of Biological and Chemical Sciences, University of the West Indies, Cave Hill Campus, Barbados (W.I.)

Abstract. Studies of early post-settlement processes in coral reef fishes have focused on small, sedentary species and have neglected the larger, more mobile, fished species. However, because recently settled fishes of both types are small and sedentary, early post-settlement processes might be similar. Here, we compare early post-settlement population dynamics of two naturally co-occurring taxa, *Sparisoma* (Scaridae), a poorly-studied medium-sized taxon important to artisanal fishers, and *Stegastes partitus* (Pomacentridae), a well-studied model species. We concurrently monitored density on three reefs in Barbados (West Indies) for 3-3.5 months following a period of high recruitment. Recruitment was >11x (*Sparisoma*) and >3x (*S. partitus*) greater than the initial number of large juveniles/adults. Recruit losses were very high (*Sparisoma* 97%; *S. partitus* 91%) for both taxa. However, the effect of recruitment on local population size differed qualitatively. After 3-3.5 months, *Sparisoma* recruitment had no effect on local juvenile density at any site, whereas *S. partitus* recruitment increased local density (by ~37%) at all sites. Our study does not support the applicability of small, model species to larger, fished ones, highlighting the need for more comparative studies.

Key words: Post-settlement, recruitment, settlement, mortality, reef fishes

Introduction

Most studies of population processes occurring within a few weeks after settlement in coral reef fishes involve a few model taxa, mainly pomacentrids, labrids and gobiids (Doherty 2002). These taxa are small, sedentary, abundant and conspicuous, offering multiple advantages as model species for ecological research (DeMartini 1998). In contrast, there are few studies of early post-settlement processes in the typically larger and more mobile species that are fished for food (Doherty 2002). It is important to know whether findings on the early post-settlement period of small, model species can be generalized.

Comparing early post-settlement population dynamics of co-occurring taxa can be particularly informative as recently settled fishes will be subject to the same environmental factors (e.g. Carr and Hixon 1995, Almany 2003). Although differences among taxa are expected, such comparisons will help reveal the magnitude and correlates of those differences.

During a year-round study on the west coast of Barbados, West Indies (Vallès et al. 2008), we identified a short concurrent period of peak recruitment in *Sparisoma* (Scaridae, likely *S. viride* + *aurofrenatum*, the two most abundant *Sparisoma* species at our sites) and *Stegastes partitus* (Pomacentridae). *Sparisoma* is a poorly-studied, medium-sized, fished taxon whereas *S. partitus* is a well-studied, small model species. This provided an opportunity to compare early post-settlement dynamics of two contrasting taxa at a time of naturally high recruitment.

Here we report the results from monitoring juvenile density of both taxa on three fringing reefs following the high recruitment period. We examine recruitment and subsequent loss rates and their ultimate effect on juvenile local population density over ~3.5 months. This is the period when both taxa are smallest and relatively sedentary, and thus, most likely to exhibit similar post-settlement effects (DeMartini 1998). We assess similarities and differences between taxa over the study period by asking: (1) what are the spatial and temporal patterns in recruitment?; (2) what is the magnitude of early post-settlement losses?; (3) what are the relative contributions of early post-settlement losses and recruitment to local density patterns?; and (4) what is the final effect of early post-settlement losses on local population density?

Materials and Methods

This study was carried out on three fringing reefs at least 2.5 km apart (Site 1: 13° 8′ 8′′N, 59° 38′ 22′′W; Site 2: 13° 11′ 48′′N, 59° 38′ 40′′W; Site 3: 13° 13′ 10′′N, 59° 38′ 41′′W), selected to capture the spatial variation in recruitment magnitude along the west coast (Vallès 2008). The habitat is a dense, patchy mixture of live and dead coral heads dominated by the star boulder coral *Montastrea annularis*, interspersed with sponges, sand and rubble. At each site, we established three permanent 6 x 6 m^2 quadrats at least 30 m apart for repeated surveys. We estimated the size of *Sparisoma* and *S. partitus* using a set of preserved specimens in a vial as a reference. We pooled the *Sparisoma* species because they are indistinguishable at first and are ecologically similar as small juveniles (Overtholtzer and Motta 1999). We allocated individuals to four non-overlapping size classes: recruits [*Sparisoma* <13mm standard length (SL); *S. partitus* <15mm SL], small juveniles (both taxa <20mm SL), medium juveniles (both taxa <30mm SL) and large juveniles/adults [*Sparisoma* <50mm SL; *S. partitus* >30mm SL, i.e. including all adults]. The upper size limit of the smallest size class (recruits) was set so that by the next survey, most recruits would have grown into the next size class (Vallès 2008). The largest size class was defined so that, by the end of the study, it included all the remaining fishes that originated from the observed recruitment. Because the recruit surveys were very time consuming, we sampled only one site per day and performed independent small juvenile surveys and large juvenile surveys. The small juvenile surveys took place every 15-d and involved recording the abundance of recruits, small and medium juveniles. The large juvenile surveys took place every 30-d and involved recording medium (again) and large juveniles/adults (Vallès 2008).

We estimated fish density over time as the mean number of individuals per quadrat (n = 3) at each site. We estimated cumulative recruitment as the sum of recruits recorded throughout the period of relatively high recruitment at each site. To assess the effect of recruitment on local density at the end of our study, we first estimated a "baseline" local density by combining the densities of the two largest size classes (medium and large juveniles) before the period of high recruitment. We calculated a "final" local density as the combined density of medium and large juveniles at the end of our study. We estimated per capita cumulative recruitment at a site by dividing cumulative recruitment by the "baseline" density.

For each taxon, we used two-factor repeated-measures ANOVAs to compare baseline and final local densities within and across sites and one-factor ANOVAs to compare cumulative recruitment across sites. Density data were square-root transformed prior to these analyses. Also, we used a two-factor repeated-measures ANOVA to assess whether recruit percent losses by the end of the study differed significantly across sites and between taxa. In all cases, quadrats were considered as random subjects and sites and taxa were considered as fixed factors.

Results

Recruitment of *Sparisoma* was similar in pattern and magnitude across all sites (Fig. 1). The bulk of recruitment occurred between the April 2 and July 2 surveys. During this period, there were two recruitment peaks at Site 1 and Site 2 during the May 2 and June 3 surveys, respectively, with the latter peak approximately 3 times as high as the former. A similar pattern was apparent at Site 3, except that the first peak merged into the second because of the asynchrony in sampling across sites. There was also substantial recruitment after July 3 at all sites, but it occurred too late to influence the juvenile density changes examined here and is not considered further.

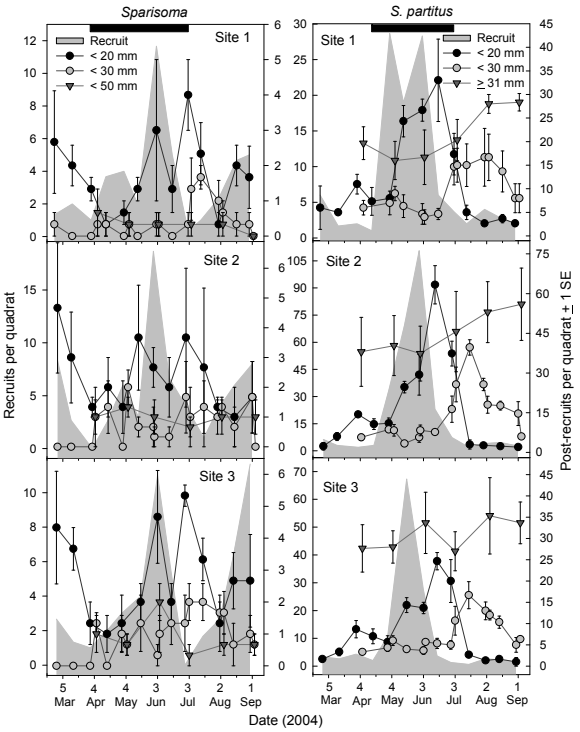

Figure 1. Average fish density on 3 permanent (36m^2) quadrats surveyed every 15-d for *Sparisoma* (left panels) and *S. partitus* (right panels) at three sites; the largest size class of both taxa was surveyed every 30-d. Separate lines represent 4 mutually exclusive size classes (mean ± 1 SE; for clarity, error bars for the recruit size class are not shown). Black horizontal bars indicate period of high recruitment monitored throughout the study.

For *Sparisoma*, recruitment pulses affected density in subsequent size classes, but were not

ultimately followed by increases in density at the end of the study. Increases in *Sparisoma* recruitment between April 2 and July 2 were followed by increases in small juvenile density (<20mm SL) at all sites (Fig. 1). Small juvenile density exhibited two apparent peaks, consistent with the two distinct previous recruitment peaks at Sites 1 and 2. There was substantial spatial variability associated with these juvenile density estimates, as indicated by the relatively large standard errors. Increases in small juvenile density were also followed by apparent increases in medium juveniles (<30 mm) at Sites 1 and 3 in the form of a single peak between July 3 and August 5. This peak was less apparent at Site 2. There was no indication of increases in large juveniles (<50 mm) at the end of the study. We found no significant evidence of an increase in final local density relative to the baseline and no significant differences among sites in local density (repeated measures ANOVA: time effect, $F = 2.520$, d.f. = 1, 6, $p = 0.164$; site effect, $F = 1.915$, d.f. = 2, 6, $p = 0.227$; time x site interaction, $F = 0.063$, d.f. = 2, 6, $p = 0.940$). In fact, final local density was slightly less than the baseline at all sites, resulting in negative net gains and percent increases at the end of the study (Table 1).

	Local density		
Taxon	Baseline	Final	% Increase
Sparisoma			
Site 1	1.0 ± 1.0	0.0 ± 0.0	-100.0
Site 2	2.0 ± 1.2	1.0 ± 0.6	-50.0
Site 3	2.3 ± 0.7	1.3 ± 0.7	-56.5
S. partitus			
Site 1	25.7 ± 2.0	36.3 ± 2.7	41.2
Site 2	43.7 ± 14.2	62.0 ± 13.9	41.9
Site 3	31.0 ± 5.5	40.0 ± 4.9	29.0
	Recruitment inputs		Recruitment
Taxon	Cumulative	Per capita	% losses
Sparisoma			
Site 1	27.7 ± 9.6	27.7	100.0 ± 0.0
Site 2	41.0 ± 23.1	20.5	96.4 ± 3.0
Site 3	26.3 ± 2.0	11.4	94.5 ± 2.7
S. partitus			
Site 1	86.7 ± 11.3	3.4	88.3 ± 5.1
Site 2	246.7 ± 51.1	5.6	92.5 ± 2.3
Site 3	112.3 ± 6.9	3.6	91.9 ± 0.8

Table 1. Above: local density of *Sparisoma* and *S. partitus* before a period of high recruitment (Baseline) and at the end of the study (Final, individuals per 36 m^2 reef quadrat ± 1 SE, N = 3) as well as the overall % increase in density. Below: cumulative recruitment (total recruits per 36 m^2 reef quadrat ± 1 SE, N = 3), per capita cumulative recruitment (cumulative recruitment divided by baseline) and percent of recruits lost by the end of the study.

Overall, cumulative recruitment over the entire April 2 – July 2 period did not differ significantly across sites (ANOVA: $F = 0.175$, d.f. = 2, 6, $p = 0.843$; Table 1), although per capita cumulative recruitment varied between 11.4 and 27.7 across sites; these latter estimates, however, are sensitive to small changes in local density because of the low baseline densities (Table 1). There was substantial variability in cumulative recruitment among quadrats within sites [average coefficient of variation within a site (CV): 56.9%].

For *S. partitus,* the bulk of recruitment occurred between the April 17 and Jul 2 surveys. There were differences among sites in the pattern and in the magnitude of recruitment (Fig. 1). At Site 1 recruitment was dominated by two distinct peaks of similar magnitude apparent in the May 2 and Jun 3 surveys. In contrast, at Sites 2 and 3, recruitment was dominated by a single large peak, apparent in the Jun 3 and May 18 surveys, respectively, possibly reflecting in part asynchrony in our surveys.

For *S. partitus*, increases in recruitment from April 17 to July 2 were sequentially followed by increases in densities of small juveniles (<20mm SL), medium juveniles (<30mm), and large juveniles/ adults near the end of the study at all sites (Fig. 1). Final local densities of *S. partitus* were significantly higher than baseline densities at all sites. There were no significant differences in local density among sites, and the magnitude of the increases did not differ across sites (repeated measures ANOVA: time effect, $F = 23.151$, d.f. = 1, 6, $p = 0.004$; site effect, $F = 1.938$, d.f. = 2, 6, $p = 0.224$; time x site interaction, $F = 0.505$, d.f. = 2, 6, $p = 0.627$, Table 1).

Overall, cumulative recruitment of *S. partitus* during the high recruitment period was more than two-fold higher at Site 2 than at the other sites (ANOVA: $F = 376.96$, d.f. = 2, 6, $p = 0.013$; Tukey test: Site 2 versus Sites 1 and 3, $p \leq 0.037$; Site 1 versus Site 3, $p = 0.667$, Table 1). Per capita cumulative recruitment varied between 3.4 and 5.6 across sites, and was at least 1.5-fold higher at Site 2 than at the other sites (Table 1). There was only moderate variability in cumulative recruitment among quadrats within a site (CV: 23.0%).

Estimated percent losses over the study period were high for both taxa, averaging 97.0% for *Sparisoma* and 90.9% for *S. partitus* across sites (Table 1). Percent losses differed significantly between taxa, but not across sites for either taxon (repeated measures ANOVA: taxon effect, $F = 5.966$, d.f. = 1, 6, $p = 0.05$; site effect, $F = 0.122$, d.f. = 2, 6, $p = 0.887$; taxon x site interaction, $F = 1.291$, d.f. = 2, 6, $p = 0.342$).

Discussion

In this study, we monitored density changes in two co-occurring taxa following a period of high recruitment. In doing so, we found both similarities

and differences between taxa in the effect of early post-settlement processes.

Similarities between taxa

Loss rates were consistently high for both taxa and most likely due to mortality. About 97% of *Sparisoma* and 91% of *S. partitus* recruits were lost from our sites 3-3.5 months after peak recruitment. Double-counting of recruits would have inflated such loss estimates; however, it is unlikely that this was a major problem because the recruit size classes were selected to allow most surviving recruits to attain the small juvenile size class before the next sampling date (Vallès 2008). Although we did not mark individuals and thus we cannot unequivocally distinguish losses due to migration and mortality, two lines of evidence suggest a negligible effect of migration. First, previous studies with marked juveniles within the size range of all those monitored in this study indicate average home range sizes considerably smaller than our quadrats (*Sparisoma*: Tolimieri 1998a, Fig 2 in Overtholzer and Motta 1999; *S. partitus*: Carr et al. 2002). Second, quadrats were placed on continuous reef so that movements in and out of the quadrats should have been balanced.

Post-settlement processes rather than recruitment variation appear to be the primary determinant of local population size for both taxa at our sites. Shulman and Ogden's (1987) sensitivity analysis of the relative effects of recruitment and post-settlement mortality on population size concluded that, at average mortality rates similar to those we observed, small changes in mortality would have a far greater effect on local juvenile population sizes than similar changes in recruitment.

We did not find significant site effects on post-settlement mortality for either taxon. However, this result warrants caution because spatial differences in post-settlement mortality of reef fishes over sites kilometers apart are common (e.g., Beukers and Jones 1997, Holbrook and Schmitt 2003). A parallel study suggested that the lack of a site effect reflected low power of our tests, given the small differences in average mortality across sites for both taxa (Vallès 2008).

Differences between taxa

The timing of recruitment peaks was generally consistent across sites for each taxon, but differed between taxa. This is consistent with the idea that settlement occurs synchronously coast-wide for each taxon in Barbados, but that temporal patterns in settlement differ between taxa (Vallès et al. 2008).

We found spatial differences in cumulative recruitment for *S. partitus* but not for *Sparisoma*. Differences in recruitment rates among sites a few kilometers apart are common (e.g, Booth et al. 2000). Here, they reflect spatial variability in cumulative settlement and/or mortality within our 15-d sampling intervals (e.g., Holbrook and Schmitt 2003). Vallès (2008) suggested that the habitat characteristics of Site 2, which differed from the other two sites, might have increased survival of *S. partitus* recruits. In contrast, the lack of spatial differences in *Sparisoma* recruitment may be due to low power associated with high within-site variability in recruit density for this taxon, compared to *S. partitus*. These differences in within-site variability suggest that relevant spatial scales of early post-settlement patterns and underlying processes (Sale 1998) differ fundamentally between these two taxa.

Cumulative recruitment over the study period was, on average, one order of magnitude higher for *S. partitus* than for *Sparisoma*. This was the case even though densities of both taxa were examined at the time of annual peak recruitment. Whether the lower *Sparisoma* recruit numbers reflect lower cumulative settlement and/or higher mortality between our 15-d surveys remains unresolved. This, however, should not affect our conclusion of significantly higher mortality for *Sparisoma* than *S. partitus* for the specimens observed over the study period.

Despite the lower number of *Sparisoma* recruits observed, per capita recruitment was considerably higher for *Sparisoma* (>11-fold) than for *S. partitus* (>3-fold). This difference was driven by the consistently low numbers of medium and large *Sparisoma* juveniles used as baseline density at our sites. Because larger size classes (>50 mm SL, including adults) of *Sparisoma* were similarly low at our sites (<2.6 ± 0.4 SE individuals per quadrat, unpublished data), including them in the baseline density would not have affected qualitatively our conclusion of substantially higher per capita recruitment for *Sparisoma* (>8-fold in the latter case).

The higher per capita recruitment of *Sparisoma* would have been expected to result in larger percent increases in local juvenile densities for this taxon, if early post-settlement processes were negligible or had a qualitatively similar effect across taxa. In contrast, the high mortality exhibited by *Sparisoma* ultimately resulted in a lack of increase in local density, whereas considerable increases (~37%) did occur for *S. partitus*. This pattern was very consistent across all sites, suggesting that our results are not an artefact of imprecise density estimates due to low counts or to insufficient quadrats per site. Thus, importantly, although mortality played a more significant role than recruitment in determining local juvenile density for both taxa, its ultimate effect on density varied qualitatively and fundamentally between taxa.

Although differences in early post-settlement mortality rates among juvenile coral reef fish species are common (Almany and Webster 2006), the mechanisms underlying such differences remain largely unexamined. In a concurrent study, Vallès (2008) suggested that differential availability of enemy-free space (Jeffries and Lawton 1984) contributes to the differences in magnitude and ultimate effect of mortality. In support of this, Vallès (2008) found that mortality of *Sparisoma* was considerably more strongly density-dependent than that of *S. partitus*, suggesting a lack of suitable refuge habitat against predators for the *Sparisoma* post-recruits at our sites (e.g., Forrester and Steele 2004).

Conclusion

The consistently low *Sparisoma* densities and the relative inconspicuousness of *Sparisoma* recruits may explain why there are few studies of recently settled *Sparisoma* (Tolimieri 1998 a,b, Paddack and Sponaugle 2008), despite the importance of this taxon in artisanal fisheries (Dalzell 1996) and reef processes (e.g., Mumby et al. 2006). Similar challenges likely explain the lack of studies on other recently settled scarids (e.g., Green 1992, Green 1998).

Bearing in mind the limitation of comparing only two taxa, we found only weak evidence that early post-settlement processes in a small model species can be applied to a larger, fished taxon studied at the same place and time. Although there were broad similarities between taxa, i.e. high mortality and high relative importance of post-settlement processes in determining local density, there were also major differences. In comparison to *S. partitus*, *Sparisoma* exhibited (1) higher spatial variability in recruitment over small scales, (2) higher per capita recruitment despite low absolute numbers of recruits, and, most importantly, (3) no increase in local densities only 3-3.5 months after a major recruitment pulse. This suggests fundamentally different local population dynamics soon after settlement. Thus, despite the challenges, our study demonstrates the need to further investigate early post-settlement processes in the larger and less numerically abundant coral reef taxa such as parrotfishes, whose abundance has important consequences for both reefs and fishers.

Fish mesograzers as gatekeepers of the species composition of coral reefs

P.M. Yoshioka

Department of Marine Sciences; University of Puerto Rico, Mayagüez

Abstract. I present preliminary evidence that intermediate-sized (~15 cm long) fish mesograzers, principally parrotfish (scarids), play a critical role in controlling the species composition of coral reefs. I describe these mesograzers as gatekeepers because they control the entry of small (newly recruited) prey individuals into coral reef communities. The gatekeeper role of fish mesograzers is based on several well-recognized features of coral reefs: (1) Fish grazing has a major impact on abundances of benthic organisms; (2) Many species have a refuge in size from grazers; and (3) Artificial substrates in offshore habitats lacking fish mesograzers are often characterized by 'fouling' species that are absent in coral reefs. I hypothesize that only small individuals of fouling (and other) species are vulnerable to fish grazers because large prey individuals are protected by structural/chemical defenses. Because of their role as gatekeepers, the reduction of fish mesograzer populations by overfishing may have profound effects on the structure of coral reef communities.

Keywords: Gatekeeper, fish mesograzers, refuge in size, structural/chemical defenses

Introduction

In this report I propose that intermediate-sized (~15 cm long) fish mesograzers have a major impact on the structure of coral reef communities by feeding on small prey individuals. I describe fish mesograzers, principally parrotfish (scarids) and possibly surgeonfish (acanthurids) and other fish taxa, as 'gatekeepers' in the sense that they control the 'entry' (survival) of newly recruited prey into coral reef communities. This hypothesis is based on several well-recognized features of coral reefs.

First, numerous studies spanning several decades (e.g. Randall 1961; Valentine et al. 2007) have demonstrated that fish grazers can control abundances of prey species. In general, previous studies have focused on herbivory by fish grazers. For instance, Randall (1965) attributed the 'halos' surrounding Caribbean reefs largely to parrotfish grazing on seagrasses. Hay (1981) found that algal species such as *Botryocadia occidentalis* and *Spyridia aculeata* are excluded from Caribbean reefs by fish grazers. Hixon and Brostoff (1996) documented the effects of fish grazing on the succession of algal species. With some exceptions (Choat el al. 2004), parrotfish grazing on invertebrates have been largely ignored except for the direct effects on corals (e.g. Rotjan and Lewis 2006) or indirect effects involving overgrowth of corals by algae (e.g. Mumby et al. 2006).

Second, it is well known that many coral reef species possess a 'refuge in size' (Dayton 1971) from grazers and predators (Hughes and Connell 1987) due to structural and chemical defenses (Jackson and Buss 1975; Harvell and Fenical 1989). However, structural and chemical defenses may be ineffective against grazers when prey individuals are small and inconspicuous. Because macrograzers (large grazers) feed on larger prey (e.g. Bellwood et al. 2006), prey species with structural/chemical defenses may be grazed upon by mesograzers but not macrograzers.

Third, artificial substrates (buoy lines, mariculture cages etc.) are often heavily colonized by so-called fouling species, such as the octocoral *Carijoa* (*Telesto*) *riisei*, that are rare or absent in coral reefs (Humann 1993). Sutherland (1974) and others have previously demonstrated that fish grazing influences the structure of the fouling community on artificial substrates in marine systems. Thus, the presence of a coral reef fouling community suggests that fish grazing has a major impact on coral reef systems.

In this report I present preliminary evidence supporting the contention that the gatekeeper role of fish mesograzers structures coral reef communities. I focus on invertebrate fouling species to exemplify the effects of fish mesograzers. I also present results of pilot experiments that indicate small individuals of such species are especially vulnerable to fish mesograzers because they do not benefit from a refuge in size.

Methods and Results

This study was largely instigated by casual observations that the invertebrate epibiota on buoy lines used to locate benthic transects in nearshore, midshelf and shelf edge coral reefs off the southwest coast of Puerto Rico (18^{o} N, 67 ^{o} W) differed from species occurring on the reefs themselves. To confirm these impressions we surveyed the invertebrates on the buoy lines. Sessile invertebrates found on the buoy lines are listed in Table 1. Several species as the octocoral *Carijoa* (*Telesto*) *riisei*, the tunicate *Ascidea nigra*, and the anemone *Aiptasia tagetes* are regarded as coral reef fouling species, and are generally restricted to artificial substrates in coral reef habitats. Other species as the sponge *Dysidea janiae* and the wing oyster *Pteria colymbus* occur frequently in reefs but were more abundant on the buoy lines.

Vertical patterns of distribution indicated that fish grazing was responsible for the presence and abundance of the epibiotic species occurring on the buoy lines. At the nearshore and midshelf reefs, only portions of buoy lines more than ~1.5 m above the substratum were colonized by sessile organisms. In contrast, epibiotic cover was low on all portions of the buoy lines at the shelf edge reefs. These vertical patterns coincided with the distribution of fish grazers. The black durgon, *Melichthys niger*, was restricted to the shelf edge reefs, and was observed feeding throughout the water column. Alternatively, parrotfish mesograzers, principally the redband parrotfish *Sparisoma aurofrenatum*, striped parrotfish *Scarus croicensis* and stoplight parrotfish *Sparisoma viride* occurred at all sites but always remained close to the bottom presumably because of the cover provided from piscivores.

As pilot experiments to test whether fish grazers were responsible for the vertical patterns of the epibiota, we lowered the upper portions of buoy lines to within about a meter of the bottom at two midshelf reefs. Almost immediately, parrotfish, wrasses, surgeonfish and butterfly fish began grazing on the buoy lines (Fig 1a). After about a week, abundances of most epibiota, especially algae, were severely reduced on the lowered portions of the buoy lines except for a colony of the sponge *Dysidea* (Fig. 1b). *Dysidea* is evidently defended chemically because a redband parrotfish *Sparisoma aurofrenatum* spit out *Dysidea* fragments soon after grazing it (Fig 1c). Hay (1991) noted that parrotfish often taste an unfamiliar item before rejecting it. Interestingly, *Sparisoma aurofrenatum* and other Caribbean parrotfish mesograzers are generally regarded as herbivores (e.g. Bruggemann et al. 1994) based on gut contents (e.g. Randall 1967). These observations indicate that various invertebrate species may be grazed upon, but not ingested, by meso-sized parrotfish. Thus, these parrotfish are probably more appropriately regarded as omnivores rather than herbivores in terms of their grazing activities.

An analogous situation with *Dysidea* occurred with a *Carijoa* colony on another lowered buoy line (Fig. 2). These results indicate that the *Dysidea* and *Carijoa* colonies had reached a refuge in size from grazers. By extension, other species occurring on the buoy lines may also benefit from a refuge in size from fish grazers.

Discussion

The maximum time that the buoy lines were on the reefs was about 3 years. This raises the alternative interpretation that the species observed in this study simply represent the initial colonizing stages of species succession, which over time will develop into a climax community dominated by scleractinian corals and other taxa. However, species such as *Carijoa* have not colonized reefs in the study area following hurricanes (Yoshioka and Yoshioka 1987) or other disturbances (pers. obs.). Additional considerations indicate that the short time span of this study is not necessarily the critical factor. For example scleractinian corals are absent on >40 year-old pier pilings locate in a sand plain habitat near Aguadilla, Puerto Rico where fish mesograzers are

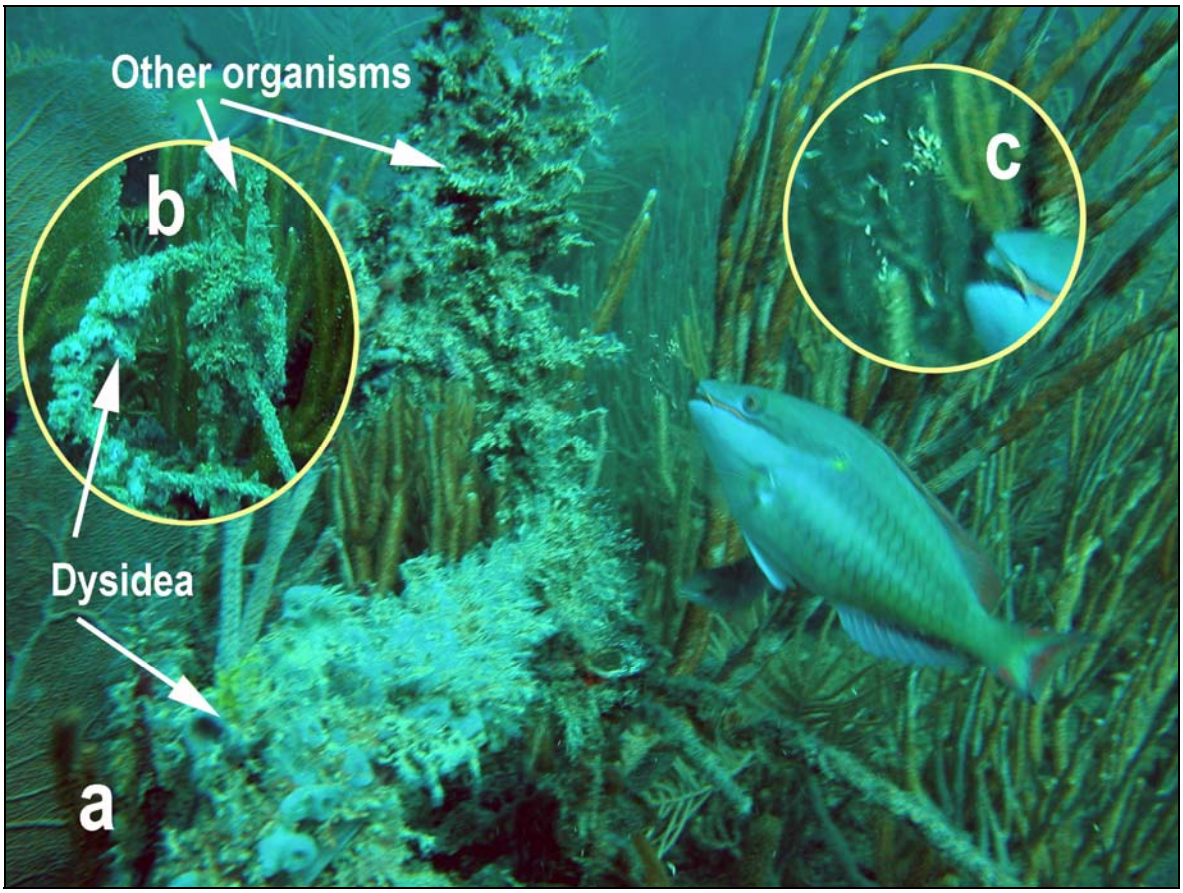

Figure 1. Fish grazing on a lowered buoy line. (a) Grazing by a redband parrotfish (*Sparisoma aurofrenatum*). (b) A *Dysidea janiae* sponge colony and other biota a week later. (c) The *S. aurofrenatum* rejecting fragments of the *Dysidea* colony.

absent (pers. obs.). Alternatively scleractinians are relatively abundant on 30 year-old metal bars in a shelf edge reef site in the study area where fish mesograzers are abundant (pers. obs.). These observations concur with the Inhibition Model of succession (Connell and Slayter 1977) wherein grazing may alter the course of succession.

With respect to terms used to describe ecologically important species, gatekeepers can viewed as a modification of the keystone species concept emphasizing prey size. Paine (1966) introduced the keystone species concept with the starfish *Pisaster ochraceus*, which controls 'post entry' abundances of the mussel *Mytilus californianus* by feeding on large (mature) individuals. In contrast gatekeepers prevent the 'entry' of prey populations into communities by feeding on small (newly settled) individuals. The emphasis on prey size is especially important if prey individuals enjoy an escape in size from grazers and predators. Paine (1976) recognized the importance of prey size by demonstrating that some *Mytilus* may grow too large for consumption by *Pisaster*.

In terms of fundamental issues in population dynamics, the gatekeeper scenario is consistent with results indicating that mortality during the early benthic life stage may be the key factor controlling variations in abundances of coral reef organisms (e.g. Yoshioka 1997). Because newly recruited prey individuals are small, the biomass of such individuals is a poor indicator of the ability of gatekeepers to control prey populations. Mumby et al. (2006) concluded that large parrotfish are more effective than meso-sized parrotfish in controlling macroalgae because of the disproportionately greater amount of biomass consumed. The gatekeeper scenario presents the alternative argument that grazing by meso-sized parrotfish may be more effective in controlling macroalgae by grazing on large numbers of small plants.

To my knowledge the gatekeeper role of fish mesograzers has received little attention in coral reef systems. In contrast, gatekeeper effects are relatively well documented in terrestrial systems. Tansley and Adamson (1925) showed that grazing by rabbits prevents the entry of shrubs and trees in grasslands of England. Ripple and Beschta (2008) demonstrated that deer grazing has prevented the successful recruitment of black oak trees for over 80 years in

Figure 2. A *Carijoa riisei* colony on a lowered buoy line. (a) Before gatekeeper grazing. (b) A week after gatekeeper grazing.

some areas of Yosemite Park. The gatekeeper scenario is reminiscent of the hypotheses of Janzen (1970) and Connell (1971) that grazing on seeds or seedlings in the vicinity of parent trees is a major factor in the maintenance of biodiversity in tropical rain forests. However, Janzen (1970) and Connell (1971) emphasize the species-specific preferences of grazers. In contrast the gatekeeper scenario proposed for coral reefs emphasizes nonselective grazing by fish mesograzers. Because the effects on nonselective grazing are more widely distributed among many prey species, relatively high levels of nonselective grazing are probably required for equivalent effects on a given prey species compared to selective grazing. This is evidently the case. Randall (1961) concluded that fish can 'overgraze' reefs, as exemplified by bare sand halos surrounding patch reefs (Randall 1965). Hay (1991) asserted that fish grazing on coral reefs equals or exceeds grazing rates for any other marine or terrestrial system. Fox and Bellwood (2008) estimated that the parrotfish *Scarus rivulatus* grazes >50% of the reef substratum on a monthly basis.

It must be emphasized that the gatekeeper scenario outlined in this report is a simplified overview of the role of fish mesograzers in coral reef systems. Many species-specific features of grazer and prey species merit attention. For example, depending upon the species involved, there is probably a sequential series of refuges in sizes from grazers (Paine 1976) rather than a single threshold in size. Assuming that structural/chemical defenses are equally effective against grazers, faster growing prey species may reach a refuge in size more quickly. Alternatively, faster growth may occur at a cost of allocating less metabolic resources to structural and chemical defenses (Paine 1977). Gatekeeper effects are probably also contingent on prey morphology. Grazing is more likely to be fatal for solitary compared to colonial organisms since damage often results in 'partial mortality' of the latter and 'complete mortality' for the former (e.g. Harvell and Suchanek 1987). Hay's (1991) observation that parrotfish taste defended prey before rejecting it is noteworthy in this regard because such taste tests may be fatal for solitary, but not colonial, organisms. Also, encrusting forms are less vulnerable than erect forms because substrate scraping by fish mesograzers is more likely to remove erect organisms. Similarly, multi-stemmed erect organisms are less vulnerable than single stemmed individuals.

Finally, I stress that, in addition to grazer-prey interactions, the gatekeeper scenario outlined herein also overlooks grazing by invertebrates and competition among prey species. Anthropogenic influences cannot be ignored because the tendency of 'fishing down the food chain' (Pauly et al. 1998) may severely reduce fish mesograzer abundances in many areas. Because the direct and indirect effects of gatekeeper grazing are largely unknown, the over harvesting of fish mesograzers may result in unforeseen and profound changes in the structure of coral reef systems.

Comparison of Sedimentation in Bays and Reefs below Developed versus Undeveloped Watersheds on St. John, US Virgin Islands

S.C. Gray[1], K.L. Gobbi[1], P.V. Narwold [1],

Abstract. Increased terrigenous runoff associated with building and development is one of the most serious threats to coral reefs. Here we evaluate how the sediment flux rates and compositions (carbonate, terrigneous [siliceous], and organic matter) differ between reefs and bays below a developed watershed compared to undeveloped watersheds on St. John, US Virgin Islands. Detailed monitoring of sedimentological processes affecting individual reefs is a critical compliment to ecological monitoring and necessary to evaluate the effectiveness of erosion mitigation strategies. During the 2007 rainy season, sediment flux rates were at least 3 and up to 73 times higher on the reefs below a developed watershed compared to reefs below an undeveloped watershed. The developed watershed sediment flux rates (3-630 mg $cm^{-2}d^{-1}$) were sometimes within range of rates previously shown to cause "severe to catastrophic" sediment stress to corals. Mean seasonal terrigenous flux rates were 15 times higher (5 vs. 0.3 mg $cm^{-2}d^{-1}$) and mean organic matter flux rates were 10 times higher (3 vs. 0.3 mg $cm^{-2}d^{-1}$) on the reefs below the developed watershed.

Key words: sedimentation, sediment flux, Virgin Islands, carbonate, TSS

Introduction

Sedimentation is one of the primary causes of coral reef degradation in the US Virgin Islands (Rogers 1990; Rogers 1998). Sedimentation stress to corals depends on the quantity, duration, and composition of sedimentation (Fabricius 2005; Philipp and Fabricius 2003; Riegl and Branch 1995). In order to effectively mitigate the potentially detrimental impacts of sedimentation to a reef, it is critical to determine the rate, mechanism, and quality (type) of sediment flux into a particular reef system.

Here we present preliminary data from an ongoing study to evaluate if development in St. John, US Virgin Islands (Fig. 1) has impacted the quantity, quality, and spatial variability of sedimentation in four bays with fringing reefs—one below a developed watershed (Fish Bay; Fig. 2A) and three below undeveloped watersheds located within the Virgin Islands National Park (VINP) (Great Lameshur, Reef, and Hawksnest Bays; Fig. 2 B-E). We addressed the following research questions: 1. What is the composition and quantity of suspended, settling (sediment trap), and accumulated (bay-floor bottom) sediments? 2. How does the sediment composition and quantity: a) vary spatially within each bay along pathways of sediment dispersal and among the bays? b) vary temporally during the study period (August-November, 2007); and c) vary between the developed and undeveloped bays? St. John, USVI is an ideal location to study the impacts of sedimentation on coral reefs because: a) there is a distinct delineation between developed and undeveloped watersheds due to the VINP (Fig. 1); b) sediment originating from land (terrigenous) is compositionally distinct (siliceous) from marine (carbonate) sediment due to the lack of terrestrial carbonate sources; and c) the fringing reefs on the island are well monitored (Rogers 1998; Rogers and Miller 2006; Edmunds 2005).

On St. John, development and construction activities outside of the VINP boundaries have brought shallow septic systems, dirt roads and impervious surfaces with increased erosion from roadbeds and cut slopes. Previous studies established a comprehensive sedimentation budget for the land area of St. John and established that there is a high "sediment delivery potential" to Fish Bay below its developed watershed (Ramos-Scharrón and MacDonald 2005; MacDonald et al. 2001, Nemeth et al. 2001).

Material and Methods

Sediment trap transects generally followed sediment runoff dispersal routes from guts (seasonal streams) into bays and across fringing reefs (Fig. 2). Bay-floor bottom sediment (upper 3 cm) transects closely replicated the bottom sediment sampling locations of Hubbard et al. (1987) in Fish, Reef and Hawksnest Bays (Fig. 2).

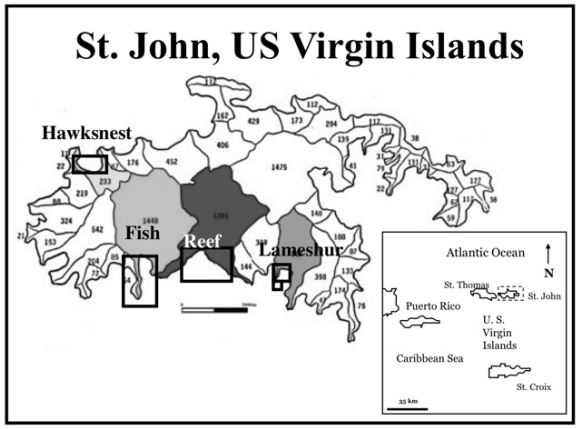

Figure 1: Map of St. John the four watersheds draining into the four study areas: Hawksnest Bay, Fish Bay, Reef Bay, and Great Lameshur Bay. Most of Fish Bay watershed is developed the other three watersheds are within the boundaries of the Virgin Islands National Park and thus considered undeveloped watersheds. The rectangles mark the locations of detailed maps (Fig. 2). Figure modified from Hubbard et al. (1987).

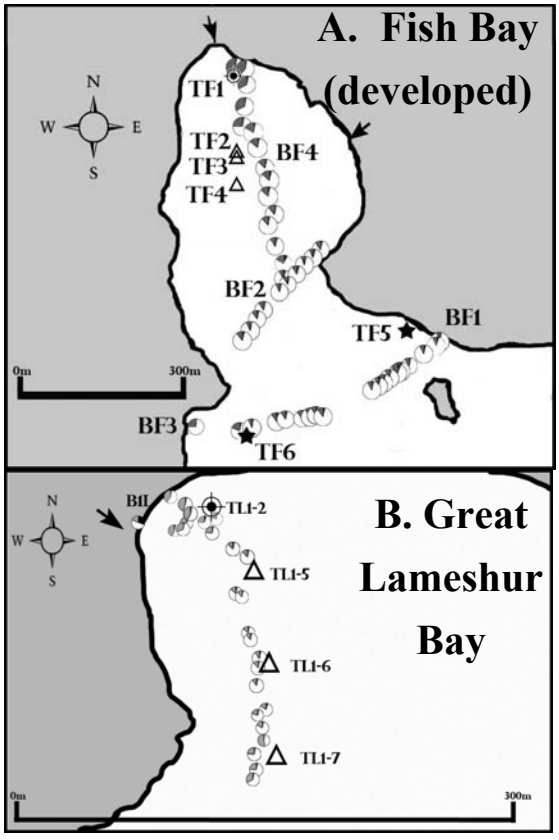

The variations in settling sediment (flux rates) were determined by deploying 14 sediment trap arrays (each with 4 exchangeable PVC tubes [length:diameter = 4:1]) attached to a metal stake 60 cm above the bay floor at 1-8 meters water depth in Fish and Great Lameshur Bays (Figs. 2A, 2B, 2C).

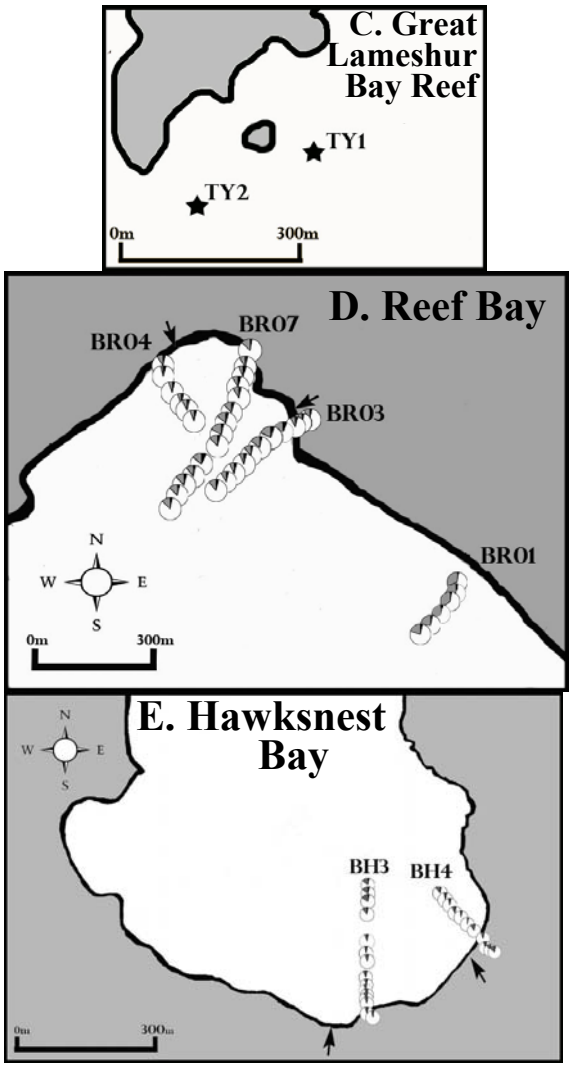

Figure 2: Maps of St. John bays showing sampling location and bay-floor bottom sediment compositions for A) Fish Bay (developed bay), B) Great Lameshur Bay, C) Yawzi Point, D) Reef Bay and E) Hawksnest Bay. Targets, triangles, and star symbols indicate the locations of sediment traps in shore, bay, and reef locations, respectively for Fish Bay (A: TF1 through TF6) and Great Lameshur Bay (B: TL1-2 through TL1-7) and Yawzi Reef (C: TY1, TY2). Pie diagrams indicate the locationsof surface bottom sampling transects in Fish (A: BF1 through BF-4), Great Lameshur (B: B1L), Reef (C: BR01, BR03, BR04, BR07) and Hawksnest (D: BH3, BH4) bays. Arrows mark the locations of guts (seasonal streams). The pie diagrams show the relative proportions of carbonate (white), terrigenous (grey) and organic matter (black) in each bottom surface sediment sample.

Sediment accumulation was monitored after 8 sampling periods (typically 12-14 days) between August-December of 2007. Sediment traps were collected and deployed at all locations within a six-hour time period. Sediment trap sediments were filtered, rinsed, dried and weighed to provide replicate measurements of the dry mass of sediment flux over the time deployed. Water samples were collected next

to each sediment trap and at the surface when sediment traps were changed (non-storm days) and filtered through a pre-combusted glass fiber filter (GF/F Whatman) to determine the total suspended sediment. The % organic matter and carbonate were determined by Loss on Ignition (LOI) at 550°C and 950° C, respectively following techniques modified from Henri et al. (2001). Additionally, a subset of samples was sieved to determine the variation in mineral composition with grain size.

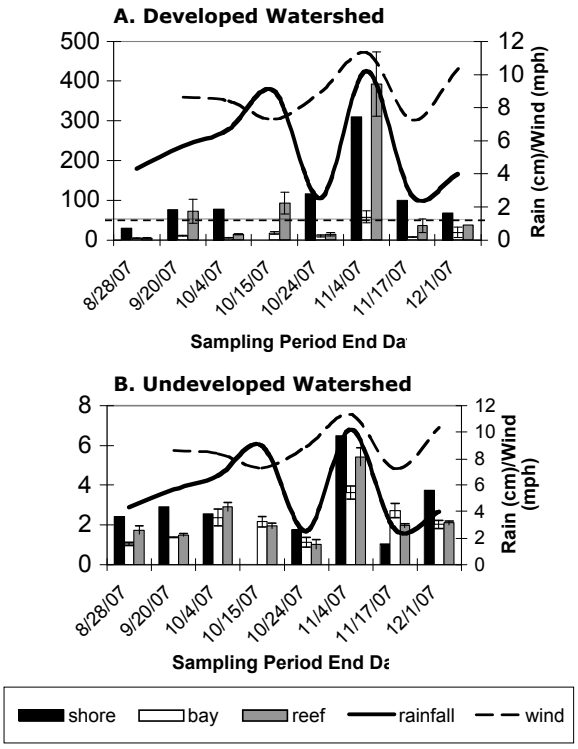

Figure 3: Variation in total sediment flux with time (Fall 2007), with total rain (cm) and mean wind speed for each sampling period in the A) developed and B) undeveloped watershed. The dashed line marks a flux rate of 50 mg $cm^{-2}d^{-1}$ above which may be detrimental to corals.

Table 1: Ratio of unsieved sediment flux below the developed watershed (Fish Bay) to unseived sediment flux below the undeveloped watershed (G. Lameshur Bay)

Sampling Period	28-Aug	20-Sep	4-Oct	15-Oct	24-Oct	4-Nov	17-Nov	1-Dec
Shore	12	26	30		66	48	94	18
Bay	4	8	2	8	8	16	3	9
Reef	3	48	5	48	14	73	18	18
Whole bay	**6**	**25**	**8**	**18**	**24**	**45**	**15**	**12**

Results

Unsieved sediment flux rates ranged from less than 1 to 400 mg $cm^{-2}d^{-1}$ (Fig. 3). The greatest sediment flux rates occurred between 10/25/07-11/4/07 when rain and mean wind speeds were highest (Fig. 3). Total mean sediment flux rates for the shore, bay, and reef stations were significantly higher in the developed

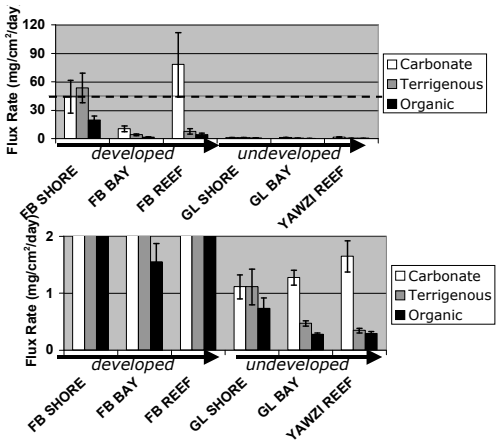

Figure 4: Mean seasonal flux rates for carbonate, terrigenous (siliceous) and organic matter were many times higher below the developed (Fish Bay) compared to the undeveloped (G. Lameshur Bay) watersheds. Arrows point from near to offshore stations. Upper and lower graphs are the same but with different vertical scales (FB: Fish Bay; GL: Great Lameshur; Yawzi Reef is in G. Lameshur Bay). The dotted line in the upper graph marks a flux rate of 50 mg $cm^{-2}d^{-1}$ above which may be detrimental to corals.

(Fish) compared to the undeveloped bay (G. Lameshur Bay) (p values = 0.0018, 0.0003, and 0.0109 for the shore, bay and reef, respectively)(Fig. 3). Compared to the flux rate at the undeveloped stations, mean sediment flux rates were up to 73, 16, and 94 times higher on the developed reef, bay and shore stations, respectively (Table 1).

The mineralogic composition of the sediments did not appear to vary much between grain size fractions for either the bottom or sediment trap samples. Carbonate, terrigenous and organic matter was found in all grain size fractions suggesting that sieving is not an appropriate way to separate terrigenous from carbonate constituents.

Carbonate was the most abundant constituent at most sediment trap stations except those nearest the shore (Fig. 4). Mean seasonal carbonate, terrigenous, and organic flux rates were up to 110, 128 and 28 times higher, respectively at the stations below the developed compared to the undeveloped watershed (Fig. 4). However, a pattern of decreasing terrigenous with increasing carbonate sedimentation with distance offshore was evident at both locations (Fig. 4).

Distinct compositional sediment flux ratios characterized sediments collected in each of the three environments (shore, bay, reef) (Fig. 5). Although the compositional flux ratios from the developed and undeveloped stations overlap, the flux ratios from the developed bay (Fish Bay) show a much wider range of values than do those from the undeveloped bay (G. Lameshur Bay) (Fig. 5).

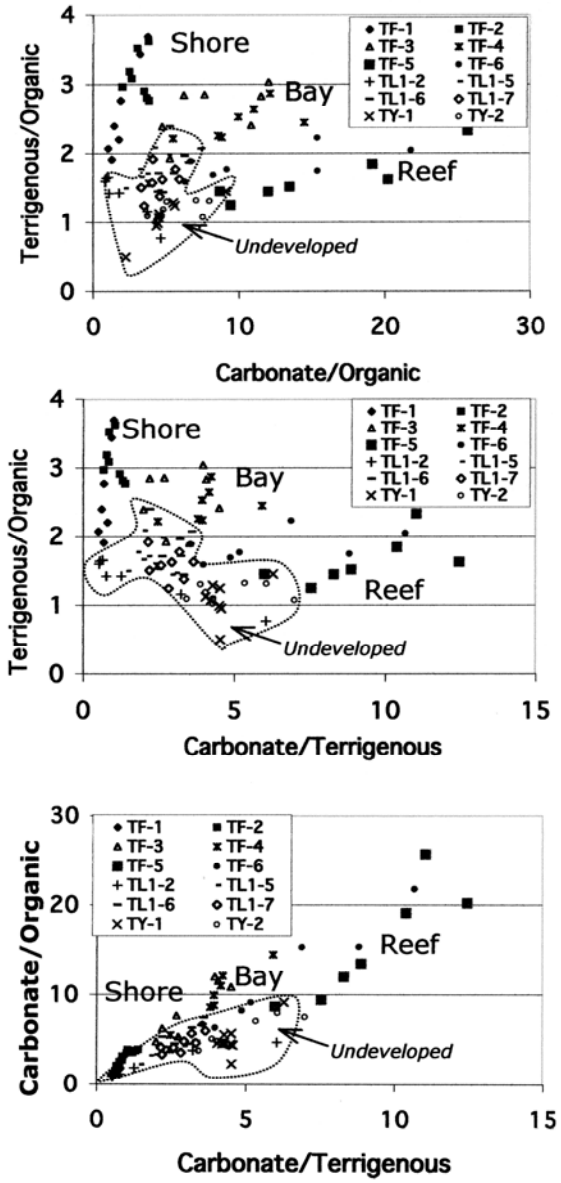

Figure 5: Distribution of compositional flux rate ratios for each sediment trap during each of 7 sampling periods indicated in Figure 3. The distribution shows distinct ratios for the reef, bay and shore environments, but a wider range of values for the developed compared to the undeveloped (within dotted lines) stations.

Like the sediment trap samples, the bay-floor bottom sediments (upper 3 cm) were comprised predominantly of carbonate, followed in abundance by terrigenous and organic matter (Fig. 6).The relative % carbonate and the ratio of carbonate to terrigenous (C_i/T) material in the bottom sediments increased with distance from the shore to the reef in both Fish and Great Lameshur Bays but not in Reef or Hawksnest Bays (Fig. 6). The percentage organic matter differed between the three sediment reservoirs (suspended: 36%-68%; trapped: 6%-23% and bottom: 2% to 4%) (Fig. 7). Mean total suspended sediment

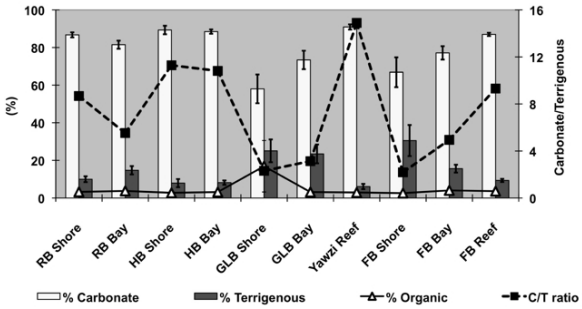

Figure 6: Composition of bottom samples (in %). The solid line marks organic matter % and the dashed line marks Carbonate/Terrigenous ratios (Ci/T). (RB: Reef Bay; HB: Hawksnest Bay; LB: Great Lameshur Bay; FB: Fish Bay).

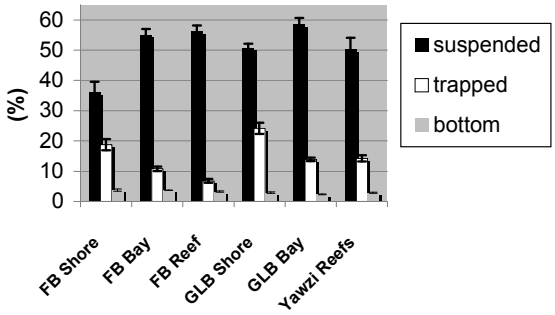

Figure 7: Mean % organic matter in three sediment reservoirs (suspended, trapped & bottom) (FB: Fish Bay; GLB: Great Lameshur Bay).

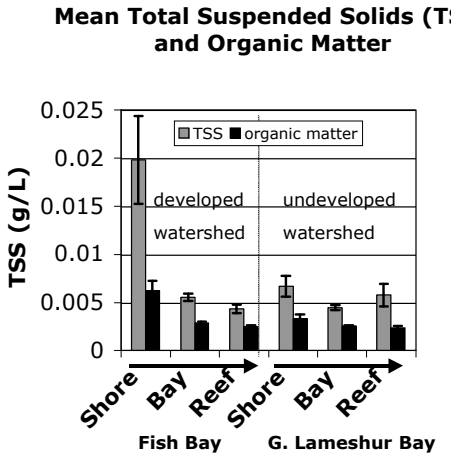

Figure 8: Mean total suspended solids (TSS) and suspended organic matter for shore, bay and reef locations below the developed and undeveloped watersheds. Arrows point from near to offshore stations. TSS and suspended organic matter were significantly higher at the shore below the developed watershed.

for the season ranged from 0.004 to 0.02 g/L and was significantly higher at the developed compared to the undeveloped shore and bay stations (p values = 0.0114 and 0.0151, respectively) (Fig. 8). The concentration of suspended organic matter was

significantly higher in the developed compared to the undeveloped bays ($p = 0.0005$).

Discussion

What can account for an up to 73-fold higher total flux and an up to 128-fold higher terrigenous flux on the Fish Bay compared to the Great Lameshur Bay (Yawzi) reefs? This difference is too large to be explained by the fact that the area of the Fish Bay watershed is three times the area of the Great Lameshur watershed. The Fish and Great Lameshur Bay watersheds have similar mean slopes, soil types, and vegetative cover. The bays are of generally similar geometry, orientation, and exposure to swells, tides and currents. The fact that the composition of the sediments in the traps is primarily carbonate suggests that the traps are likely collecting sediments that have been resuspended by waves and currents in addition to terrigenous sediments delivered directly in suspension from terrestrial runoff. There is greater availability of terrigenous sediment in Fish Bay (developed) compared to Great Lameshur Bay (undeveloped). We are conducting further studies to evaluate the sediment availability to resuspension and have deployed current meters to quantify the specific relationship between current velocity and sediment flux into the traps.

These data clearly show that the corals at Fish Bay reef are under significantly greater sediment stress than the corals at Great Lameshur (Yawzi) reef. The total sediment flux rates at Great Lameshur Bay reef were consistent with rates previously recorded for reefs that were not subjected to human activities (<1-10 mg $cm^{-2}d^{-1}$: Rogers, 1990). However, the sediment flux rates on the Fish Bay reef were high enough to be potentially dangerous to the reefs. Pastorak and Bilyard (1985) suggested that flux rates of 10-50 mg $cm^{-2}d^{-1}$ and > 50 mg $cm^{-2}d^{-1}$ could cause "moderate to severe" and "severe to catastrophic" sediment stress, respectively. Sediment flux rates on Fish Bay reefs were higher than 50 mg $cm^{-2}d^{-1}$ during three of the 8 sampling periods and above 300 mg $cm^{-2}d^{-1}$ during one. These high flux rates (>100 mg $cm^{-2}d^{-1}$) have been shown to kill exposed coral tissue within a few days (Riegl and Branch 1995) or reduce photosynthetic yields (Philipp and Fabricius 2003). Studies suggest that organic sediment may be particularly harmful to corals (Fabricius 2005). The reef below the developed watershed had organic flux rates up to 28 times higher than the reef below the undeveloped watershed.

Though bay-to-bay flux rate differences were quite dramatic, compositional differences between fluxing sediments were more subtle and were revealed by examining within-bay and bay-to-bay differences in the relative ratios of constituent flux rates.

Comparisons of both quantity and compositions of the suspended and bay floor bottom sediments did not reveal striking differences between the developed and the undeveloped locations. Our preliminary comparisons show that the composition of bottom sediments has not systematically changed (within 5% relative %) since the Hubbard et al. (1987) sediment survey despite intensive development in the area. Continued research through the 2008 season is underway as well as textural and geochemical analyses of the 2007 sediments.

Spatial patterns of reproductive synchrony by four genera of tropical green seaweed across a latitudinal gradient in the Caribbean.

K. E. Clifton[1]

1) Lewis and Clark College, Department of Biology, 0165 SW Palatine Hill Rd., Portland OR 97219, USA

Abstract. Spatial and temporal patterns of reproductive effort are an especially significant feature of fertilization success for virtually all broadcast spawning organisms. While most research efforts on this topic have focused on varying temporal scales of reproductive synchrony (i.e., diel, lunar, and seasonal scales), patterns of reproductive synchrony on varying spatial scales (i.e. from meters to hundreds of kilometers) are less well studied. Simultaneous investigations of sexual reproduction by tropical green seaweeds (e.g., *Caulerpa, Halimeda, Penicillus, Udotea*) across a latitudinal gradient in the Caribbean (Panama, U.S. Virgin Islands, Florida) reveal patterns of reproductive synchrony on different spatial scales. Within a region, spatial synchrony often extends beyond local populations (meters to tens of meters) to at least scales of tens of kilometers, however, such synchrony is not maintained across larger (hundreds of kilometer) spatial scales. Relative synchrony within and between genera is maintained across this larger latitudinal gradient, however. Reproductive seasonality also shows an interaction with latitude for these seaweeds, with shorter, temporally delayed seasons of reproductive activity occurring at higher latitudes.

Key words: Broadcast spawning, Coral reef, Green algae, *Halimeda*, *Penicillus, Udotea*.

Introduction

Broadcast spawning, the release of gametes directly into the water column, is a common reproductive tactic for a diverse array of benthic marine organisms including stony corals (e.g., Harrison *et. al*. 1984; Baird et. al., 2001), soft corals (e.g., Lasker et al. 1996), echinoderms (e.g., Babcock and Mundy 1992; Levitan 1991, 1995), green algae (e.g., Clifton 1997, Clifton and Clifton 1998), sponges (e.g., Hoppe and Reichert 1987; Fell 1993; Ritson-Williams et al. 2005), and mollusks (e.g., Shelley and Southgate 1988; Lucas 1994; Kenchington et al. 2006). Synchrony of gamete release in both space and time is a consistent feature of these reproductive events, as organisms that match the timing of their gamete release with those of neighbors should enjoy increased fertilization success. Understanding the proximate cues that organize these reproductive events, as well as their ecological and evolutionary consequences remains a topic of interest to coral reef biologists.

Broadcast spawning can be examined at diel, lunar, and seasonal temporal scales. Patterns of reproductive timing are becoming increasingly better known, particularly for well-studied broadcast spawners like the stony corals (e.g., Tanner 1996, Guest 2004, Guest et al., 2005, Mangubhi and Harrison 2008). Studies of spatial patterns of reproduction have received less attention (although see: Oliver et al. 1988; Willis et al. 1985; Hughes et al. 2000; and Baird et al. 2002). As might be expected, even less is currently known about the degree to which temporal patterns of broadcast spawning behavior are preserved or altered at increasingly larger spatial scales.

This paper describes temporal and spatial patterns of broadcast spawning behavior for 4 genera of Caribbean seaweed (Bryopsidales) across a latitudinal gradient of 15°. Diel and seasonal patterns of gamete release for these algae at a single location (Caribbean Panama) are already described (Clifton and Clifton 1998). When compared with more northerly sites (St Croix, US Virgin Islands and Key Largo, Florida), changes in the diel timing of gamete release shifted with changes in the onset of sunrise. At the most northern site seasonal shifts in reproductive activity correlated with an annual change in water temperatures. Interspecific patterns of reproduction observed at local spatial scales were preserved over latitudinal gradients. This suggests that, at any one location, the relative contribution that various endogenous and environmental factors ultimately make to the timing of reproduction will vary, depending on the temporal scale being examined.

Material and Methods

Four genera of green macroalgae in the Order Bryopsidales (*Halimeda*, *Caulerpa*, *Penicillus*, and

Udotea) were observed for this study. All are common and abundant within shallow tropical marine communities across the Caribbean, including coral reef, seagrass bed, and mangrove habitat. Algae were identified to species using Littler and Littler (2000) and Littler *et. al.,* (1989).

Reproductive activity was quantified from daily surveys of shallow marine habitats at one of three sites: Kuna Yala, Panama (9°33' N, 78°56'W); Tague Bay, St Croix, US Virgin Islands (17°45' N, 64°36'W; and Key Largo, Florida (25°05' N, 80°24'W). Observers snorkeled along proscribed routes for 30–60 minutes, examining a minimum of 500 thalli for macroscopic evidence of impending sexual reproduction. This occurs 12–24 hrs prior to gamete release for seaweeds in the genus *Halimeda* and *Caulerpa*, 36–48 hrs for *Penicillus* and *Rhypocephalus*, and 60-72 hrs for *Udotea* (Clifton and Clifton 1998). Time of gamete release was recorded during direct observations of undisturbed seaweeds during the early morning spawning period. Initial time and duration of gamete release was noted following the methods of Clifton and Clifton (1998). Seawater temperatures for Panama and St Croix were measured using "StowAway Tidbit" automated temperature loggers (Onset Computer Corp). Temperatures from Florida were downloaded from archived NOAA Data Buoy information (www.ndbc.noaa.gov).

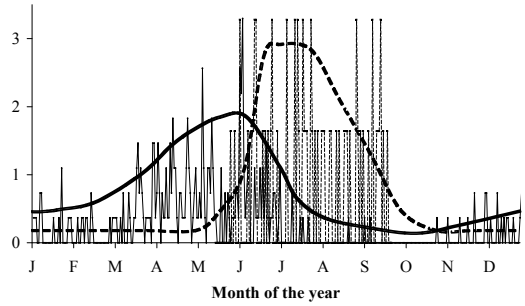

Figure 1: Seasonal patterns of sexual reproduction by green seaweeds at two sites: Panama (solid lines) and Florida (dashed lines).

Results

Seasonal patterns of reproduction

Populations of tropical green macroalgae across the Caribbean showed different seasonal patterns of reproductive activity. At 9° N latitude (Panama), reproduction occurred almost year-round, with a broadly seasonal peak from April to July that roughly corresponds to the onset of the region's annual wet season (Fig. 1). At 15° N latitude (Florida), reproductive activity occurred later in the year, between the months of June and September (Fig. 1). In general, a larger proportion of the population participated in a reproductive event on any given day at the more northern site (K. Clifton, *unpub data*), suggesting that, on an annual basis, total levels of reproduction between the two sites may not be that different. The seasonal peak of reproduction at the northern site correlated with the period of time when local water temperatures exceeded 27°C (Fig. 2).

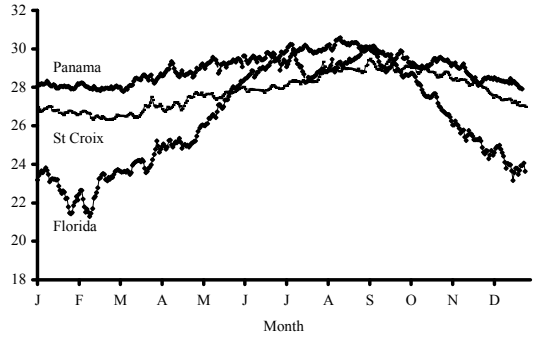

Figure 2: Seasonal variance in surface temperature at three Caribbean sites. The period of time when temperatures exceed 27°C is shorter and later in the year at higher latitudes. See text for details.

Sub-seasonal patterns of reproduction

The sub-seasonal scheduling of sexual reproduction by tropical green seaweeds does not show any obvious relationship to lunar or tidal cycles (Clifton 1997). There is, however, some regularity of spawning effort and this differs from one species to the next. For some species, a subset of the population reproduces every few days and this pattern is maintained across sites that differ in latitude. For example, the alga *Caulerpa cupressoides* reproduced roughly once every 7 days during the seasonal peak of reproduction in 1999 at all sites (Fig. 3).

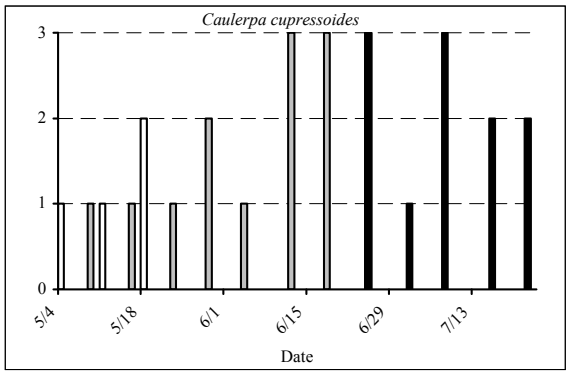

Figure 3: Patterns of sub-seasonal reproduction for *Caulerpa cupressoides* at three Caribbean sites. Color scheme as follows: open bars = Panama; shaded = St. Croix, USVI; black = Key Largo, Florida. "Extent of population" represents the percent of the population participating in the reproductive event as follows: 1: < 1% of the population; 2: 1% - 3%; 3: > 3% of the population.

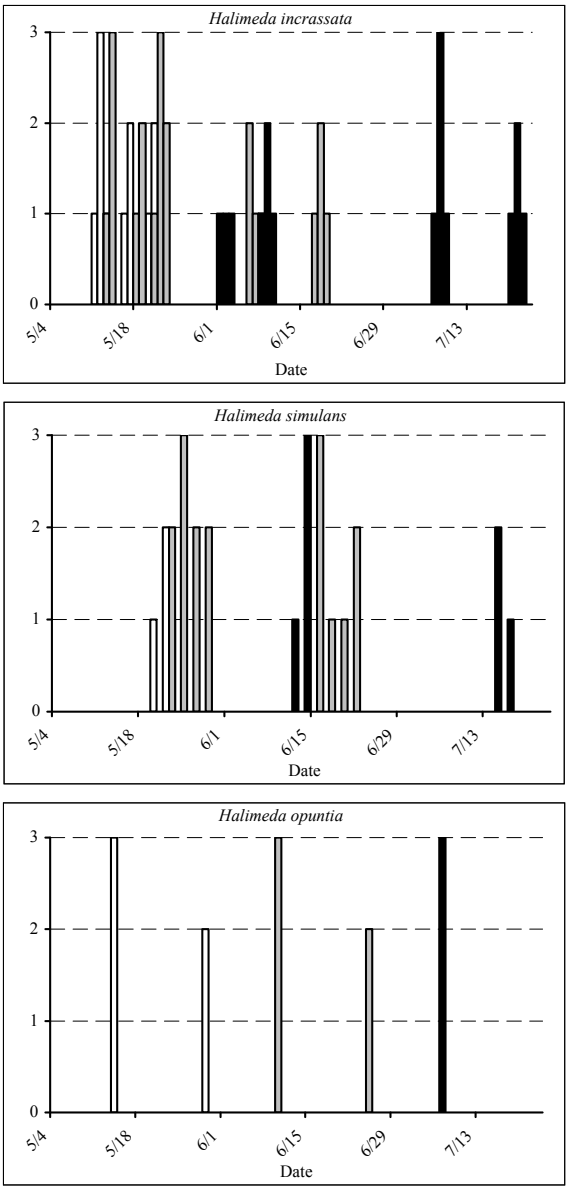

Figure 4: Patterns of sub-seasonal reproduction for three species of *Halimeda* observed during a three-month period in 1999 at three sites in the Caribbean. *H. incrassata* and *H. simulans* are closely related species that occupy similar soft bottom habitats. *H. opuntia* is a larger, sprawling species that occurs on reefs and in soft bottom habitats. Specific dates of observation: Panama: 5/4-6/29/99; St Croix, USVI: 5/4-6/28/99; Florida: 5/20-7/23/99. Shading and axes as in Fig. 3.

Other species showed quite different sub-seasonal patterns of reproductive activity. For example: *Halimeda incrassata* tended to reproduce in three day pulses, separated by gaps of 7 – 14 days; *Halimeda simulans* tended to reproduce every other day at somewhat varied levels of intensity for a several reproductive events, with less regular gaps between these pulses; and *Halimeda opuntia* tended to reproduce roughly every 14 days, with some variance around this tendency (Fig. 4). As with *Caulerpa cupressoides*, however, interspecific differences in the sub-seasonal timing of reproduction by different species of *Halimeda* were essentially preserved at all three sites, despite their differing latitude. Similar trends were found for four species of *Penicillus* (*P. capitatus*, *P. dumetosus, P. lamouroxii*, and *P. pyriformes*) as well as *Udotea flabellum*. *P. capitatus* and *P. lamorouxii* generally showed highly overlapping sub-seasonal patterns of reproduction (i.e., they showed a strong tendency to reproduce on the same day) as did the heterogeneric pair of *P. pyriformes* and *U. flabellum*. This latter pair tended to release gametes 2-3 days following bouts of reproduction by the former pair and, as with other species, this trend was preserved across a latitudinal gradient.

Diel patterns of reproduction

Tropical green seaweeds release their gametes just prior to sunrise and the precise timing of this release is both highly predictable and species-specific (Clifton 1997, Clifton and Clifton 1998). For all species the timing of gamete release, relative to sunrise, was observed to shift to an earlier time with increasing latitude.

For example, the timing of gamete release for *Halimeda tuna* at the three Caribbean sites shifted approximately 30 seconds earlier for every degree of change in latitude across the 15 degree change in latitude across the region (Fig. 5). This trend was further supported by a single observation of gamete release by *H. tuna* from the more northerly, Adriatic Sea. A quadratic curve fitted to the mean time of release at each location ($y = -0.011x^2 - 0.107x - 11.37$) provided an excellent fit to these points (Fig. 5; $R^2 = 1.00$; n = 4; $p = 0.01$).

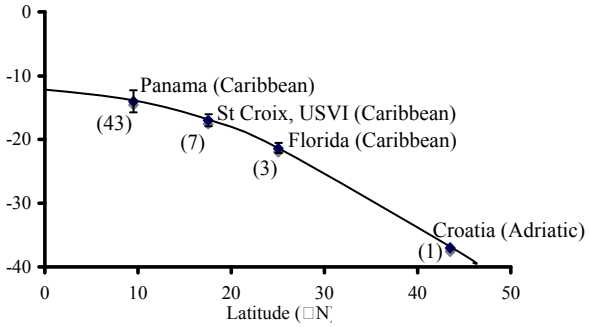

Figure 5: Quadratic curve fit to the mean time of gamete release for *Halimeda tuna*, relative to sunrise and as a function of latitude. Data from Panama are cumulative from observations in 1996-1998. Observations at the other three sites were made in 1998-1999. The single observation of gamete release in the Adriatic (43°9' N, 16°11'E) was provided by Ante Zuljevic. Sample sizes are in parentheses and error bars are ± 2 standard errors.

Discussion

As a general result, diel and seasonal patterns of broadcast spawning by tropical green seaweeds were found to shift with latitude, while sub-seasonal patterns of reproductive behavior were relatively unchanged, irrespective of distance from the equator. These results provide clues as to the proximate mechanisms structuring patterns of temporal synchrony in these broadcast spawning organisms.

Changes in the seasonal peak of reproduction by tropical green seaweeds to a later time of year in higher latitudes follows the trend seen in some stony corals, although simultaneous observations at several sites spanning large latitudinal distances are not common (see Baird et al. 2002; Wilson and Harrison, 2003; Nozawa, et al. 2006). For tropical green algae, the strong correspondence of the onset and cessation of seasonal reproductive activity at higher latitudes with the presence of water temperatures greater than 27°C strongly implicates a role for temperature as an important determinant of the timing of seasonal patterns of reproduction.

Unlike many other broadcast spawning organisms, tropical green seaweeds do not show lunar or tidal patterns of sub-seasonal reproduction (Clifton 1997, Clifton and Clifton 1998), yet the data presented here suggest there is some temporal structure to their patterns of reproduction from day to day. Although these are quite variable from species to species, the relative duration of inter-spawn intervals does show some within species specificity, as well as some intriguing patterns of correlation between species pairs such as *Penicillus capitatus* and *P. lamouroxii* or *P. pyriformes* and *Udotea flabellum*. While the proximate cues that help organize sub-seasonal bouts of reproduction for these seaweeds is not revealed from the results here, the consistency of pattern that was retained, even across a latitudinal gradient of 15° suggests that such organizing cues do exist and the results described here should encourage further study of this topic.

On a diel temporal scale, the shift to an earlier time of gamete release with an increase in latitude supports the idea that changing levels of pre-dawn light are an important component of what structures the exact timing of gamete release on a given morning. The curvilinear aspect of the relationship between time of release and latitude, as shown for *Halimeda tuna* in Fig 5, suggests that the trigger for gamete release may be more a function of cumulative light exposure rather than an absolute threshold of light level.

While much work remains to be done on the proximate mechanisms that organize and promote bouts of gamete release by broadcast spawning organisms, the results presented here suggest that there is utility in the study of gamete release that is done on a variety of temporal and spatial scales. As such, future studies in this arena should be encouraged.

Abstract. Seasonality in reproduction in temperate marine invertebrates is well recognized, but reproduction at the equator where environmental variability is lower is typically assumed to be continuous. This paper reviews studies of the reproductive cycles of four species of sea urchins and one species of sea cucumber to test for seasonality and sexual synchrony along the Kenyan coast (1^0S - 5^0S). Gonad index measurements and macro and microscopic observations of gonads were used to evaluate monthly changes in gonad growth. The urchin *Echinometra mathaei* and sea cucumber *Holothuria arenacava* displayed a seasonal reproductive pattern with gametogenesis commencing in July during the southeast monsoons and spawning peaking between March-April during the northeast monsoons. Monthly temperature and light significantly correlated with gonad index in these species but light displayed a stronger response. The sympatric urchins *Diadema savignyi* and *D. setosum* had a monthly gametogenic cycle with *D. savignyi* spawning after full moon and *D. setosum* spawning in the last quarter. These species also showed seasonal gonad growth with *D. savignyi* following a pattern similar to *E. mathaei.* The life history strategies of these species included a high level of sexual synchrony and spawning at the time most favorable for larval growth.

Key words: Reproductive seasonality, sea cucumbers, sea urchins.

Introduction

Reproduction in echinoids and holothuroids is reported to display seasonal reproductive cycles with temperate species generally having discrete spawning periods and tropical species reproducing for longer periods throughout the year (Orton 1920, Giese and Pearse 1974, Smiley et al. 1991). Reproductive activity was therefore hypothesized to be less synchronized and continuous throughout the year at the equator since environmental variability is less pronounced (Orton 1920, Giese and Pearse 1974, Pearse 1974). However, few studies have compared the reproduction of several species of echinoderms at the same location at the equator (Pearse 1974).

Gametogenesis in echinoderms has been correlated with environmental factors such as water temperature and photoperiod, while spawning is suggested to be triggered by changes in water temperature, food availability, light intensity, water turbulence, salinity and phytoplankton blooms (Krishnaswamy and Krishnan 1967, Himmelman 1980, Engstrom 1980, Cameron and Fankboner 1986, Pearse et al. 1986, Ramofafia et al. 2000, 2003). These factors often vary spatially and temporally and are suggested to exercise a strong selective pressure promoting reproductive synchrony and success.

The Kenyan coast occurs at the equator (1^0S – 5^0S) but is exposed to monsoonal seasonality with varying oceanographic conditions of temperature, light, and productivity (McClanahan 1988). This makes it suitable for testing the effects of monsoonal seasonality on breeding patterns of marine invertebrates at the equator. This paper reviews studies of four species of sea urchins and one species of sea cucumber that were carried out on the Kenyan coast (Muthiga, 2003, 2005, Muthiga and Jaccarini 2005, Muthiga 2006), to test the hypothesis that reproduction will show a weak seasonal pattern at the equator due to reduced variability of the environmental factors that control gametogenesis and spawning.

Materials and methods

The studies were undertaken at Kanamai an unprotected reef and Ras Iwatine within the Mombasa marine reserve located between 3^0S and 5^0S. Study sites are described in Muthiga and Jaccarini (2005), and Muthiga (2005, 2006). At each site ten to twenty specimen were collected each month for a period of one to three

years between 1986 and 1998 (Table 1). The annual reproductive pattern was assessed by tracking gonad growth by measuring the monthly gonad index calculated as the monthly mean ratio of the wet weight of the gonad, relative to the wet weight of the individual for sea urchins (Gonor 1972) and of the wet weight of the body wall for sea cucumbers (Conand 1981). Macroscopic and microscopic observations were also made of the gonad to verify the sex and maturity stages.

Table 1. The locations, species, year of study and SST (mean annual) of the study sites on the Kenyan coast. The mean annual SST is calculated from NOAA data.

Reef	Lat	Species	Year	SST
Kanamai	3° 55'	*T. gratilla*	87-88	26.9
Kanamai	3° 55'	*D. savignyi*	92-93	26.9
Kanamai	3° 55'	*D. setosum*	92-93	26.9
Kanamai	3° 55'	*E. mathaei*	92-94	26.9
Ras Iwatine	4° 70'	*H. arenacava*	97-98	27.1

The relationship between individual size and gonad growth was determined by a correlation between the gonad index (%) and the weight (g) of individuals. The level of synchrony in reproduction between the sexes was determined by a correlation between the mean monthly gonad index of female and male individuals.

Temperature and light measurements were obtained from NOAA climatic data for each location and averaged monthly from 1985 to 1994 and correlated against mean monthly gonad indices for each species. The northeast monsoons start in October and end in April, while the southeast monsoons occur from May to September on the Kenyan coast (McClanahan 1988).

Lunar periodicity was measured in the sea urchins by inducing individuals to spawn using KCl every 2 to 4 days during the peak reproductive period. The gametogenic cycle was also tracked by calculating the mean gonad index every 2 – 4 days for several lunar cycles (new moon = lunar day 0) during the peak period of reproduction.

Results

There was a significant and positive relationship between individual gonad weight and body size for all species ($p < 0.0001$ for all species) and no significant relationship between gonad index and body size for any of the species (Table 2).

The pattern of gonad growth in *E. mathaei* measured through mean monthly gonad indices was seasonal and showed that gametogenesis commenced in July when gonad indices were 3.03 ± 0.54% (sem). The gonad index then gradually increased to peak at 8.03 ± 0.21% between January and February at the peak of the northeast monsoons (Fig. 1). There was no significant difference between the overall average gonad index of females and male *E. mathaei* (Table 3.).

Table 2. The relationship between body size (weight for sea urchins and body wall weight for the sea cucumbers) and the gonad weight, and gonad index of individuals for the species sampled. For each comparison, the correlation coefficient r, and the sample size (in brackets) are provided.

Species	Size vs. gonad weight	Size vs. gonad index
T. gratilla	0.53 (163) *	0.08 ns
D. savignyi	0.60 (270)*	0.14 ns
D. setosum	0.56 (276)*	0.15 ns
E. mathaei	0.41 (100) *	0.03 ns
H. arenacava	0.51 (720)*	0.30 ns

* = $p < 0.0001$; the sample sizes are the same for both comparisons

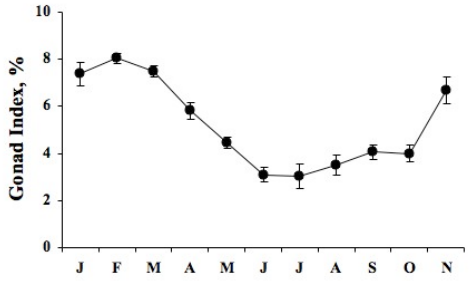

Figure 1. The seasonal variation in the gonad index of *Echinometra mathaei* (± sem) collected at Kanamai (3^0S) between 1992 and 1994.

Monthly spawning induction showed that many individuals of both sexes were ready to spawn by October when 50% of female and 60% of male gonads had ova or sperm filling more than 50% of the gonadal lumen (Fig. 2).

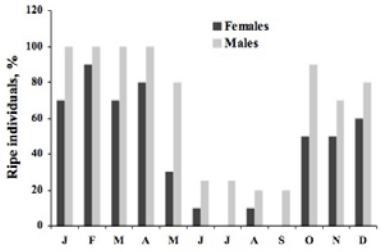

Figure 2: The percent of ripe males and females of *Echinometra mathaei* collected at Kanamai between 1992 and 1994. Ripe individuals were classified as those with gonadal lumen > 50% full of sperm or ova (Pearse 1969).

Histological observations of the gonads showed that the ovarian tubules of *E. mathaei* had in-growing nutritive phagocytes in July, new small oocytes appeared in August and ova were

present from October to May. Males were ripe for ~8 months since sperm filled more than 50% of gonadal lumen from October to May (Fig. 2), while females were ripe for a period of 5 months (December to April).

The pattern of gonad growth was also seasonal in the sea cucumber *Holothuria arenacava* (Fig. 3). Mean monthly gonad indices peaked in March when gonad indices were 13.55 ± 0.45%. The main spawning commenced by August and was completed by May when gonad indices were reduced by more than 90% and all individuals had very small immature gonads.

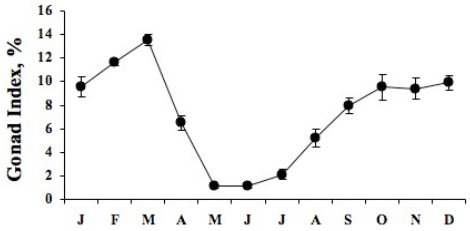

Figure 3: The seasonal variation in the gonad index of *Holothuria arenacava* (± sem) collected at Ras Iwatine (4^{0}S) on the Kenyan coast.

Macroscopic examination of the gonad tubules indicated that gametogenesis commenced in July when small oocytes were present in the gonad tubules. Large oocytes were evident and filling gonad tubules by September.

The sympatric species *Diadema savignyi* and *D. setosum,* showed a monthly gametogenic cycle (Fig. 4.). *Diadema savignyi* had a tightly synchronized gametogenic cycle with ~ 90% of individuals producing copious gametes on lunar day 18 a few days after the full moon.

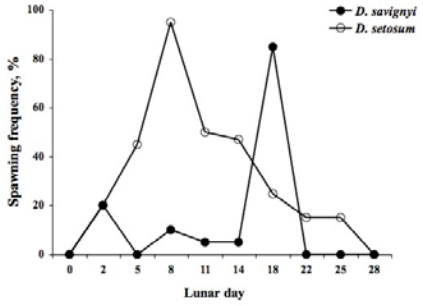

Figure 4: The spawning frequency of *Diadema savignyi* and *D. setosum* induced to spawn with injections of KCl. Spawning induction was carried out every 2 – 4 days for 3 complete lunar cycles. Lunar day 0 = new moon.

Microscopic examination of the gonads showed mature ova in gonadal lumen between lunar day 10 and 17. Spawning in *D. setosum* was less synchronized among individuals and occurred a few days after the new moon for several days (lunar day 5 – 14) with a peak at lunar day 8. Microscopic examination showed ova in individuals from lunar day 0 to lunar day 7.

The annual pattern of gonad growth of *D. savignyi* and *D. setosum* was also seasonal but varied between these sympatric species (Fig. 5).

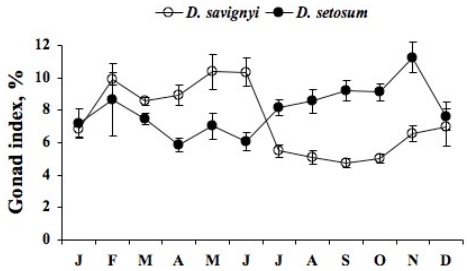

Figure 5: The seasonal variation in the gonad index of *Diadema savignyi* and *D. setosum* (± sem) collected at Kanamai (3^{0}S) on the Kenyan coast.

Although mature gametes were present every month in both species, reproductive output varied and gonad indices were highest between February and June in *D. savignyi* (9.9 – 10.4%) while peak gonad indices occurred between September and November in *D. setosum* (9.2 - 11.3%).

The annual pattern of gonad growth in the sea urchin *Tripneustes gratilla* showed a weak seasonal pattern (Fig. 6) and gonad indices ranged from 2.62 ± 0.23% in January gradually increasing to 4.90 ± 0.64% in July. There was a ~ 30% decrease in gonad index in August.

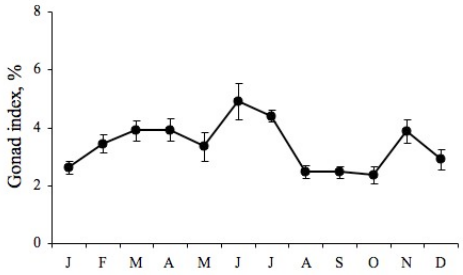

Figure 6: The seasonal variation in the gonad index of *Tripneustes gratilla* (mean monthly ± sem) collected at Kanamai (3^{0}S) on the Kenyan coast.

Macroscopic examination of the gonads revealed that most individuals had 'runny' gonads that could easily be sexed through the presence of female or male gametes. The proportion of individuals within each monthly sample with ripe gonads ranged from 0% to 75% and did not correlate significantly with mean monthly gonad index (r = 0.33).

The gonad indices of *T. gratilla* collected every few days over a period of two lunar cycles from April to July indicated lunar periodicity. Gonad indices increased from 3% on lunar day 0 (new moon) to 8% by lunar day 8 and lowered to < 2% between lunar days 18 to 25 during the last quarter of the moon.

The relationship between the reproductive activity of males and females measured as the average monthly gonad index in *E. mathaei, T. gratilla* and *H. arenacava* was highly significant but showed a lower level of synchrony in *D. savignyi* and *D. setosum* (Table 3.)

Table 3. The average gonad index of female and male individuals and the relationship between mean monthly gonad index of females and of males of the studied species. For the monthly comparison between sexes, the correlation coefficient r are provided.

Species	Females (GI %)	Males (GI%)	F vs. M r
T. gratilla	5.46±0.42 (55)	5.47±0.54 (47)	0.91** (12)
D. savignyi	8.03±0.35 (36)	7.03±0.37 (37)	0.92 * (12)
D. setosum	9.39±0.6 (31)	8.86±0.56 (28)	0.80 * (12)
E. mathaei	6.94±0.22 (246)	7.16±0.21 (205)	0.75 ** (12)
H. arenacava	9.8±0.3 (240)	6.8±0.4 (196)	0.79 ** (12)

* = $p < 0.05$ level; ** = $p < 0.01$; samples sizes in brackets

The relationship between temperature and light was variable between species. *Echinometra* mathaei and *H. arenacava* showed significant relationships with both temperature and light but the relationship with light showing the stronger response in both species (Table 4).

Table 4. The relationship between mean monthly gonad index of each species and mean monthly SST (°C), and mean monthly light (Einstein/m^2/day) at the studied sites. For each comparison, the correlation coefficient r, and the p value (in brackets) are provided.

Species	Gonad index vs. temperature	Gonad index vs. Light
T. gratilla	-0.20 (0.52) ns	-0.43 (0.16) ns
D. savignyi	0.64 (0.02) ns	- 0.19 (0.55) ns
D. setosum	- 0.39 (0.20) ns	0.39 (0.2) ns
E. mathaei	0.69 (< 0.01)	0.75 (< 0.01)
H. arenacava	0.71 (0.01)	0.94 (< 0.0001)

There was no significant relationship between the monthly gonad index and temperature and light in *D. savignyi*, *D. setosum* and *T. gratilla*. The highest gonad indices in both *D. savignyi* and *D. setosum* however coincided with the months with the highest temperatures and light.

Discussion

The gonad index was variable across all sizes and did not show a correlation with body size in the species studied. This indicates that gonad index is independent of body size in these species and is a reliable predictor of reproductive condition as has been shown for other species of sea urchins (Gonor 1972, Muthiga 1996) and sea cucumbers (Drumm and Loneragan 2005).

The pattern of gonad growth was seasonal in all the species with *E. mathaei* and *H. arenacava* showing a particularly strong pattern that included complete spawning and resorption of gonads in May-June during the southeast monsoons followed by a period of gonad growth that peaked between February and March during the northeast monsoons.

This pattern is comparable to marine invertebrate species that occur at higher latitudes (Smiley et al. 1991, Ramofafia 2000, Drumm and Loneragan 2005) and does not support the hypothesis that marine organisms at the equator will breed year round (Orton 1920; Giese and Pearse 1974; Smiley et al. 1991). Previous studies in the tropics but at latitudes higher than the equator have also shown seasonal patterns of reproduction in sea urchins and sea cucumbers (Pearse 1969, 1974, Reichenbach 1999, Ramofafia et al. 2000, 2003).

The pattern of gonad growth in *D. savignyi*, *D. setosum* and *T. gratilla* also showed an annual pattern but in all three species, the presence of gonads and gametes in individuals during most months of the year indicated that individuals were reaching reproductive maturity and spawning at different times of the year. Gonad growth however was higher during the northeast monsoons for *D. savignyi* and *T. gratilla* and started earlier during the southeast monsoons in *D. setosum* and peaked at the beginning of the northeast monsoons.

Temperature and light, the main environmental factors that have been shown to trigger gametogenesis and spawning in marine invertebrates showed relatively small variations on the Kenyan coast. However, in at least two of the studied species, gonad growth correlated significantly with light and temperature suggesting that these factors played a role in controlling reproduction in these species.

The presence of reproductive periodicity functions to allow individuals of a population to take advantage of the best time of the year to produce young and synchronize spawning (Lessios 1981). In the studied species male and females were highly synchronized and spawning

activity generally peaked at or just prior to the time when phytoplankton concentrations peaked on the Kenyan coast.

Although the monthly ranges of temperature and light at the studied sites were low (± ~4^{0}C; ~20 Einstein/m^2/day), the changes were predictable and followed a strong seasonal pattern that is driven by the monsoons (McClanahan 1988). This predictability could act as a reliable cue for the onset of gametogenesis and spawning.

The fact that the sympatric *Diadema* species – that also showed a monthly spawning pattern, displayed a seasonal pattern of gonad growth and the presence of seasonal reproduction in fish (Ntiba and Jaccarini 1990), in sea cucumbers (Kithakeni and Ndaro 2002, Muthiga per comm.) and recruitment of barnacles and oysters (Ruwa and Polk 1994) suggests that monsoonal seasonality maybe the proximate driver of life history strategies of marine invertebrates on the east African coast.

Abstract. The reproductive ecology of extant equatorial eastern Pacific (EEP) zooxanthellate scleractinian corals is examined relative to projected global warming conditions. Life history characteristics and patterns of abundance and distribution of 13 recently studied species in Costa Rica, Panamá, and the Galápagos Islands are considered. Twelve of these are broadcast spawners, which are numerically abundant, widely distributed, and the principal EEP reef builders. *Porites panamensis*, the lone brooder, is a small nodular coral with a restricted distribution. The majority of the broadcasting species are highly fecund, release gametes during large parts of the year, and produce sexual recruits that appear to disperse relatively far to diverse habitats. Asexual fragmentation is also common in most EEP broadcasting species compared to *P. panamensis*. We hypothesize that diverse habitats and varying environmental conditions (e.g., upwelling/nonupwelling centers, varying thermal conditions, high/low turbidity, high/low productivity, El Niño/La Niña activity) increase the probability of survival of sexual recruits and the asexual fragments of broadcasting species. Surviving refuge populations could serve as sources to repopulate degraded coral communities. The EEP reef coral fauna, dominantly broadcasting species, possess traits (e.g., high fecundity, widely dispersed) that could help resist environmental challenges during global warming.

Key words: Broadcast-spawning coral survival, eastern Pacific.

Introduction

During multiple and diverse disturbances to coral reefs since the early 1980s, the perception has gained favor that corals brooding and releasing planula larvae have higher survival rates and subsequent success in reproduction and recruitment to degraded reefs than broadcast-spawning corals. This view was especially supported by studies in the Caribbean (e.g., Aronson and Precht 2001; Knowlton 2001). Following hurricanes, coral disease outbreaks, bleaching events and other disturbances, it was found that brooding species on many reefs demonstrated higher rates of survivorship and recruitment than broadcasting species. Relatively small colonies of brooding species have replaced major frame-building species on several western Atlantic coral reefs.

The cool/turbid and elevated nutrient conditions associated with upwelling in early Miocene time was postulated to have led to the demise of about one-half of the coral genera in the Caribbean. From an analysis of the coral genera that survived these changing conditions during the Caribbean Oligocene-Miocene extinction event, Edinger and Risk (1995) concluded that brooding corals were disproportionately favored over broadcasting coral taxa. Edinger and Risk (1995) extended their analysis to the modern eastern Pacific, suggesting that the upwelling environments in the equatorial eastern Pacific (EEP) would also favor the survival of brooding corals. At the time of Edinger and Risk's (1995) study, little was known of the reproductive modes of eastern Pacific corals. Several studies are now available, providing information for a re-examination of the relative benefits of brooding and broadcasting reproductive modes in marginal reef settings. Here we examine these contrasting modes of reproduction in the EEP region, in the context of coral bleaching caused by elevated temperature stress.

Material and Methods

This re-analysis is based on the reproductive biology and ecology of EEP zooxanthellate scleractinian corals, chiefly from study sites in Costa Rica, Panamá and the Galápagos Islands (Fig. 1). Life history information was compiled from Glynn et al (1991 1994 1996 2000); Colley et al (2002 2006); and unpublished observations. The 13 species considered, of the 23 known species constituting the EEP fauna, are the principal reef-building corals. This study examines physical environmental conditions,

reproductive traits, spatial/seasonal reproductive patterns, and geographic distributions from the published literature and unpublished sources.

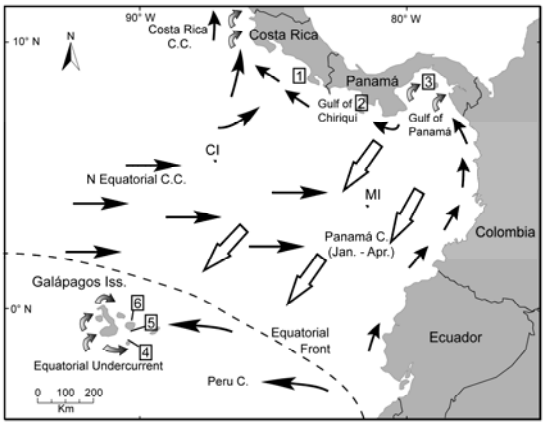

Figure 1: Coastal and offshore island sites of the equatorial eastern Pacific region. Numbered study sites: 1 – Caño Is, Costa Rica; 2 – Uva Is, Panamá; 3 – Saboga Is, Panamá; 4 – Floreana Is, 5 – Santa Cruz Is, 6 – Canal de Itabaca, Galápagos Islands. Locations of surface currents and upwelling centers (small thick arrows off NW Costa Rica, in Gulf of Panamá and W sector of Galápagos Iss) are noted. Key: Costa Rica C.C., Costa Rican Coastal Current; N Equatorial C.C., North Equatorial Counter Current; Panamá C., seasonal Panamá Current (large open arrows); Peru C., Peru Current; CI, Cocos Island; MI, Malpelo Island.

Results

Of the 13 studied coral species, 12 spawn gametes (Table 1). These include the major frame-building species *Porites lobata*, *Pavona gigantea*, *Pavona clavus* and *Gardineroseris planulata*, which construct massive (dome-like) colonies, and *Pocillopora damicornis* and *Pocillopora elegans* that form branching colonies. Massive colonies attain 1 m in diameter and occasionally 2-3 m. Branching colonies range from 15 to 30 cm in diameter, and when growing in juxtaposition, form vertically-oriented and interlocking branches ≥ 1 m in height. Although no data exist for *Pocillopora inflata* from the majority of study sites, they spawned gametes immediately after collection in the Pearl Islands, Panamá (pers obs). *Porites panamensis* is the only brooding species. It typically forms small (5-10 cm max diam) nodular colonies, and occasionally colonies up to 30 cm in diameter that encrust basalt substrates.

Five broadcast-spawning species and the brooder *Porites panamensis* are gonochoric. Six broadcast spawning species are hermaphroditic: two pocilloporids are simultaneous hermaphrodites and four agariciids are sequential cosexual hermaphrodites. Sequential cosexual hermaphrodites are those species that display multiple cycles of gamete development during a breeding season; maturation of the sexes alternates in tissues, revealing early stage gametes of one sex with late stage gametes of the opposite sex (Policansky 1982). Asexual fragmentation occurs occasionally to commonly in all species except *Porites panamensis* and *Psammocora superficialis*.

Table 1. Life history traits of presently studied EEP zooxanthellate coral species. SG-spawns gametes, BP-broods planulae; sexuality: G-gonochoric, H-hermaphroditic, simul-simultaneous, seq, sequential cosexual; Growth form (greatest dimension): nod-nodular, mas-massive, branch-branching, encrust-encrusting, pet-petaloid, sm-small (5-10cm), med-medium (10-30cm), lg-large (0.3-2m); Asexual reproduction: rare-seldom observed, occ-occasional, sometimes observed, com-common, frequently observed. Environmental conditions: Gulf of Panamá, seasonal upwelling; Gulf of Chiriquí, nonupwelling, seasonal shoaling of thermocline; Galápagos Islands, seasonally cool. Numbers in bold indicate number of months during the calendar year when Stage IV oocytes were present in histological sections. Numbers in parentheses indicate number of non-overlapping months when Stages I-III oocytes were present. n/a, species not present, too uncommon or rare to sample, or not sampled seasonally.

The temporal presence of mature ovaries in broadcast-spawners was highly variable, depending on locality, which in turn was strongly influenced by seasonal thermal conditions. In general, species in the thermally stable Gulf of Chiriquí were reproductively active from 3 to 11 months of the year. Six of the 10

broadcast-spawners in the Galápagos Islands contained mature oocytes from 4 to 7 months of the year. Zooxanthellae were present in both the oocytes of *Porites panamensis* and three broadcast-spawning species, namely *Porites lobata, Pocillopora damicornis* and *Pocillopora elegans*. In the seasonally upwelling (late December-through April) Gulf of Panamá, planulae were present in *P. panamensis* during 8 nonupwelling months, and year round in the Gulf of Chiriquí where temperature conditions were high and more stable. Where quantified, fecundity estimates were high for six broadcast-spawning species: *Porites lobata, Pavona clavus* (unpub data), *Pavona varians*, *Pavona gigantea*, *Pavona chiriquiensis* and *Gardineroseris planulata*, and the brooder *Porites panamensis*.

Porites panamensis has the narrowest distribution of all 13 species. Within the eastern Pacific region it is known only from mainland localities and the Revilla Gigedo Islands, Mexico (Table 2). The majority of the broadcast-spawning species are present at several eastern Pacific localities, including all major oceanic island sites (Garzón-Ferreira and Pinzón-C 1999; Glynn and Ault 2000; Guzmán and Cortés 2007). Eleven of the 12 EEP broadcast-spawners are also present in the Indo-Pacific region. *Pocillopora inflata* occurs in the Phoenix Islands (D Obura, pers comm) and *Pavona chiriquiensis* at Wallace Island (M Pichon, pers comm). While P. damicornis occurs from the eastern Pacific across the tropical Indo-Pacific, it is a broadcast-spawner in the eastern Pacific and releases brooded planulae throughout the remainder of its range (Richmond and Hunter 1990).

A global survey of the number of coral taxa that experienced major bleaching disturbances during the past few decades shows relatively high survival and recovery of broadcast-spawning species (Table 3, Baker et al in press). High proportions of the dominant recovering corals in the Indian Ocean, eastern Pacific, central W/S Pacific, and Arabian Gulf were broadcast spawning species. Even in the western Atlantic reductions in the relative abundances of broadcast-spawners were markedly less than brooding species after the 2005 coral bleaching/disease event in the U.S. Virgin Islands (Rogers et al 2008). Agariciid brooders showed the greatest declines in abundance.

Discussion

Present information on the reproductive traits of EEP reef-building corals indicates that the great majority, 12 of 13 studied species, are broadcast-spawners. Szmant (1986) hypothesized that the survival and recruitment of Caribbean brooding species should be favored in habitats that are subject to frequent disturbances. Such species are typically small, short-lived, reach reproductive maturity at an early age, iteroparous (with 9-12 reproductive cycles yr-1), produce lecithotrophic larvae, host zooxanthellae, and undergo local settlement/recruitment. Some observations have purported to show that the planulae of brooders can potentially disperse over long distances, thanks to the presence of energy-rich food stores and phototrophic zooxanthellae (e.g., Richmond 1987). Even some brooders with zooxanthellate larvae, however, have been shown to have short dispersal ranges with the majority recruiting to within 100 m of their natal colony (Underwood et al 2007). The literature review of Harrison and Wallace (1990) indicates a long pelagic phase for the larvae of broadcast spawning corals compared with brooded planulae. In addition, a recent study quantifying the survival of larvae of broadcast spawners suggests a greater potential for long-distance dispersal than previously recognized (Graham et al 2008).

Some recent studies in the western Atlantic appear to support Szmant's (1986) prediction. For example, brooding poritid and agariciid species have replaced broadcasting acroporid and faviid species on reefs in Jamaica (Hughes 1994) and Belize (Aronson and Precht 2001). In Brazil, small brooding recruits of siderastreid, agariciid and faviid species were much more abundant after unknown disturbances (possibly storm waves and mechanical damage by divers) than broadcast-spawning mussid corals (Kikuchi et al 2003). However, a survey of recovering corals from a bleaching event in the US Virgin Islands revealed a higher survivorship of broadcasting over brooding species (Rogers et al 2008). In this study, it was found that broadcast-spawning species in the *Montastraea annularis* complex remained community dominants whereas brooding *Agaricia agaricites* declined dramatically in abundance.

Edinger and Risk (1995) inferred that the majority of coral genera that survived increased upwelling in the early Miocene in the Caribbean were brooding species, compared with broadcast-spawning species that suffered high rates of extinction. They assumed that the surviving genera of brooding and broadcasting corals followed the same developmental patterns observed in present-day taxa. It is necessary to exercise caution when inferring the reproductive mode of coral species within particular genera. For example, the genera *Porites*, *Acropora* and *Pocillopora* contain species that exhibit brooding and broadcast spawning. *Porites* and *Acropora* were classified as taxa exhibiting a mixed mode of reproduction. In the Caribbean, all *Porites* spp. are brooders, but in the Indo-Pacific most *Porites* spp. are broadcast spawners. Even within the morphospecies *Pocillopora damicornis*, broadcast spawning occurs in the EEP and planula release in the Indo-Pacific (Richmond 1990). Ongoing studies have revealed that the major reef-building corals in the EEP are broadcast spawners and not brooding species as suggested by Edinger and Risk (1995).

During both the 1982-83 and 1997-98 ENSO bleaching events in Costa Rica (Guzmán et al., 1987) and Panamá (Glynn, 1990; Glynn et al 2001) whole colony mortality was high in *Porites panamensis* compared with partial colony mortality in several large broadcast spawning species. *Porites panamensis* demonstrated a delayed bleaching/mortality response, 2-3 months after most other scleractinian species, and disappeared from several monitored sites as well as two entire coral reefs for 3 to 5 years (Glynn 1984). This brooding species was considered regionally endangered by Glynn et al (2001).

An important issue relating to the survival of reef corals of divergent reproductive modes is the discrepancy in time and space on evolutionary and ecological scales. In this analysis, we have considered the survival of particular reproductive groups over evolutionary time. The ecological data supporting these survival patterns, i.e. which groups recover following disturbances over periods of years to a few decades, are at variance with the long-term trends. In some cases, brooders seem to demonstrate higher survival (e.g. Jamaica, Belize, Brazil), supporting Szmant's (1986) predictions, while in other cases broadcast spawning species appear to be more successful at surviving disturbances (e.g. Virgin Islands, Indian Ocean, eastern Pacific). This difference may be due in part to disturbance type (chronic vs acute), site specificity or previous history (Hughes 1989). Over evolutionary time, however, the variability of responses may become reduced with the life history traits of some taxa promoting long-term survival.

Considering the localized settlement behavior of *Porites panamensis* and the widespread distribution of EEP broadcast spawners, we conclude that EEP species with the latter reproductive mode have a high potential for dispersal. In addition, the EEP offers a wide variety of environmental settings for colonization: upwelling/nonupwelling centers, variable temperature regimes, carbonate/basalt substrates, wet/dry season conditions, high/low

turbidity, high/low productivity, and El Niño/La Niña activity. Environmental circumstances that could enhance coral survival during stressful warming events are upwelling centers, shallow thermocline development, and high tidal amplitude with attendant strong current flow (Riegl and Piller 2003). The variety of major surface currents should also promote a relatively high degree of connectivity between EEP localities. In conclusion, the life history traits of broadcast spawning corals, in combination with an opportunity to colonize diverse EEP environments, would appear to enhance the survival of broadcast-spawning corals following large-scale disturbances in this region.

Multi-specific coral spawning in spring and autumn in far north-western Australia

N. L. Rosser[1], A.H. Baird[2]

1) RPS Environment, 290 Churchill Ave, Subiaco, Western Australia 6004, Australia
2) ARC Centre of Excellence for Coral Reef Studies, James Cook University, Townsville, Queensland, Australia

Abstract. In Australia, 'mass' coral spawning, where hundreds of coral colonies and numerous species release gametes on the same night, typically occurs in October/November (spring) on the Great Barrier Reef, and in March/April (autumn) on the Western Australian coast. To assess if Western Australian corals also spawn in spring, surveys of the reproductive status of *Acropora* were conducted at over 10 sites in two locations in north-western Australia, spanning over 1000 km and six degrees of latitude. This research found that 39% of *Acropora* species spawned in spring at the most northerly location and 7% of *Acropora* species spawned in spring at the more southerly location. This is the first time such a significant reproductive event in spring has been recorded in spring in Western Australia. While the causal mechanisms driving this second spawning period are likely to be complex, suitable environmental conditions in both spring and autumn might allow for two reproductive seasons on the far north-western Australian coast. This study suggests that the conditions that are suitable for reproduction in October/November are more favorable at the Bonaparte Archipelago than further south at the Dampier Archipelago.

Key words: biannual spawning, coral reefs, spawning synchrony, north-west Australia

Introduction

Multi-specific 'mass' coral spawning, where hundreds of zooxanthellate scleractinian corals synchronously release gametes on the same night (Harrison et al. 1984), has been found to occur on many coral reefs around the world; however, the timing and synchrony of spawning varies considerably among different geographic locations and regions (Guest et al. 2005a).

In some regions around the world, synchronous multi-specific spawning is concentrated over 2-3 months of the year (e.g. Japan, Hayashibara et al. 1993; Central Pacific, Kenyon 2008), while in other regions the length of the spawning period can extend for 5-7 months (e.g. Palau, Penland et al. 2004; Kenya, Mangubhai & Harrison 2008).

In Australia, the traditional paradigm has been that synchronous mass spawning largely occurs annually over 1-2 months, in spring (October and/or November) on the Great Barrier Reef (GBR) (Willis et al. 1985; Babcock et al. 1986), and in autumn (March and/or April) on the Western Australian coast (Simpson 1991; Babcock et al. 1994), and that most colonies of many species spawn over a few consecutive nights.

While corals on many reefs around Australia do display remarkable synchrony in their reproductive timing, there are also some noteworthy exceptions. On the GBR, a number of *Acropora* species are known to spawn several months after the mass spawning period (Wallace 1985; Kojis and Quinn 1981; Wolstenholme 2004), while others may spawn twice a year (Stobart et al. 1992). There is also evidence that in the *Acropora*, some spawning occurs following *every* full moon between October and February on the central GBR (Baird 2006).

Similarly on Western Australian reefs, synchronous spawning of multiple species has been recorded up to two months either side of the mass spawning period (Stewart 1993; Smith 1993; Rosser 2005), and a number of *Acropora* species have also been found spawning in spring (Rosser and Gilmour 2008).

Several environmental factors have been cited as influencing the timing of mass spawning in different regions. The most common include sea temperature, for its assumed role in the growth and maturation of gametes and larvae (Giese and Pearse 1974; Willis et al. 1985; Oliver et al. 1988); rainfall, for its reduction in salinity and physical impact upon gametes (Harrison et al. 1984; Mendes and Woodley 2002); tides and/or calm sea conditions, for their role in promoting fertilization and/or dispersal (Babcock et al. 1986; Hayashibara et al. 1993); and solar insolation, for its role in synchronising gametogenesis (Penland et al. 2004; van Woesik et al. 2006).

The extent to which corals participate in synchronous multi-specific spawning outside the traditional 'mass spawning period' was the focus of this research. We investigated the proportion of *Acropora* species that were likely to spawn in spring (October/November) at two locations in north-western Australia.

Material and Methods

This research was conducted at the Dampier Archipelago (20º28'S, 116º37'E) and the Bonaparte Archipelago (14º30'S, 125º0'E) (Fig. 1) in north-western Australia. Expeditions to each location were conducted independently by the authors (Rosser, Bonaparte; Baird, Dampier) as part of larger projects.

Reproductive samples were collected between 18 and 20 March at Bonaparte, and between 26 and 28 March at Dampier (full moon 2 April 2007); and between 9 and 10 October at Dampier, and between 23 and 25 October at Bonaparte (full moon 26 October 2007). Coral spawning typically occurs 8-10 days after the full moon in Western Australia so it was anticipated that spawning would occur in April and November.

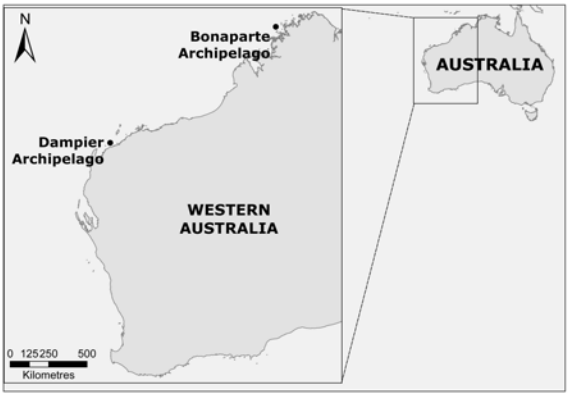

Figure 1: Location of the study sites in Western Australia

Surveys of the reproductive status of corals from the genus *Acropora* were conducted at both locations. Reproductive status was assessed by breaking up to three branches of each colony of approximately 30 species of *Acropora* (up to 700 colonies were sampled at each location). Colonies were assessed *in-situ* and scored for the presence of pigmented eggs prior to the full moon. This sampling methodology has been used previously by Harrison et al. (1984) and Baird et al. (2002) as pigmented eggs represent mature eggs that will be released shortly after the next full moon.

A lower number of *Acropora* species were sampled at the Dampier Archipelago (14 species) than at the Bonaparte Archipelago (31 species) in October due to the species assemblages in each location being different; the Bonaparte Archipelago has a much higher species diversity than the Dampier Archipelago.

Geophysical parameters including mean monthly records of sea surface temperature (SST), wind speed and rainfall for 2007 (sourced from Remote Sensing Systems satellites sponsored by NASA http://www.remss.com/) were also compared between the two locations.

Results

In the Bonaparte Archipelago, 12 species of *Acropora* (39% of the *Acropora* species sampled) were recorded with pigmented eggs in October 2007, indicating that they were likely to spawn in November (Fig. 2). Dampier Archipelago however showed a different result, with only one *Acropora* species (7% of *Acropora* species sampled) recorded with pigmented eggs in October (Fig. 2).

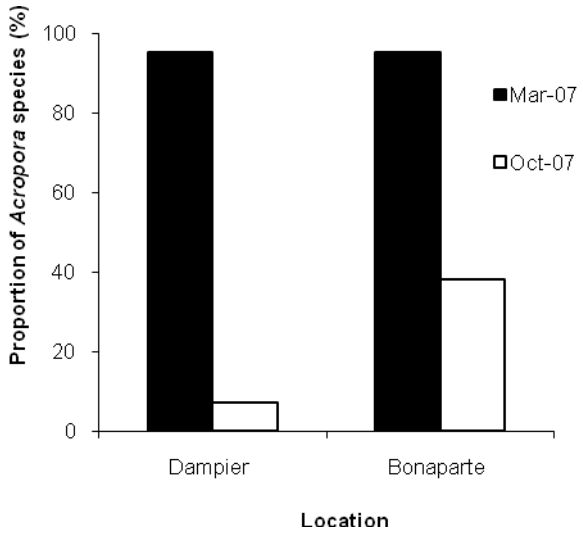

Figure 2: The proportion of *Acropora* species with pigmented eggs in March and October 2007 at the two study locations.

Ten species were sampled at both sites; of these, four species had mature colonies (40%) at Bonaparte, while only one species *Acropora humilis* (10%) had mature colonies at Dampier. For one of the four mature species at Bonaparte (*A. latistella*), only two colonies were sampled at Dampier (Table 1). For the other two mature species at Bonaparte, *A. digitifera* and *A. loripes*, 35 and 11 colonies were sampled respectively at Dampier but no colonies were found containing mature oocytes. At Bonaparte, 8 other species had colonies with mature oocytes, but these species were not sampled at Dampier (Table 1).

The proportion of colonies within each species that had pigmented eggs in October at Bonaparte Archipelago was highly variable, ranging from 5-100% (Table 1), with a mean of 47% ±7.6 (SE).

Interestingly, at both Dampier and Bonaparte Archipelagos, 95% of *Acropora* species had pigmented eggs in March 2007 (Fig. 2).

A comparison of geophysical parameters across the two locations showed that SST was higher at the Bonaparte Archipelago than at the Dampier Archipelago, though the annual variation in SST was similar at both locations (4ºC).

Average monthly wind speed showed that in the Bonaparte Archipelago there were two distinct periods of low winds: March and October, while in the Dampier Archipelago wind speed was more constant, with a drop in wind speed occurring only in March.

Monthly rainfall patterns were similar at both locations, with the highest monthly rainfall occurring in March (at both locations).

Discussion

Here we provide clear evidence that at the Bonaparte Archipelago in Western Australia, multi-specific spawning is occurring twice a year, in both spring and autumn, with March/April being the primary spawning period and October/November being the secondary spawning period.

Our finding that a substantial proportion of the *Acropora* populations in north-western Australia participate in a second mass spawning event is of particular interest because previously, the secondary spawning event was considered to be relatively minor. Rosser and Gilmour (2008) found that 36% of *Acropora* species were likely to spawn between October and December at Barrow Island (in north Western Australia), and the mean proportion of colonies in each species participating was 27% ± 7.4 (SE). The spring spawning event at Bonaparte Archipelago described here, involves a greater number of *Acropora* species and almost double the proportion of colonies from each species participating.

Multi-specific spawning periods in both spring and autumn have been recorded in other regions, however the number of species and colonies involved is generally much lower (Wolstenholme 2004; Guest et al. 2005b).

We provide no evidence to suggest that individual colonies spawned twice, because most *Acropora* species are considered to have a single annual gametogenic cycle (Wallace 1985; Mangubhai and Harrison 2008; Rosser & Gilmour 2008). Rather, we suggest that different individuals within a single species spawn at different times.

The most northerly location, Bonaparte Archipelago, had a higher number of *Acropora* species spawning in November 2007 than at the southern location in the Dampier Archipelago. While a greater number of species was sampled at Bonaparte than at Dampier due to different species assemblages at each location, the trend in this data suggests that the magnitude of spring spawning is greater at

Bonaparte than at Dampier. The causal mechanisms resulting in differential spawning patterns are likely to be complex and have yet to be fully resolved. The comparison of geophysical data between the two locations may, however, provide some insight into causal mechanisms.

In October and November, sea surface temperature was 2-3ºC lower at the Dampier Archipelago than at the Bonaparte Archipelago, and this may explain why the magnitude of spawning was much lower at Dampier in November. A meta-analysis of coral spawning in the Caribbean showed that monthly mean SST has a significant relationship with gamete release, therefore suggesting that an optimal temperature is necessary for gamete maturation and that this temperature window may be quite narrow (van Woesik et al. 2006). In this respect, it is possible that sea surface temperature is sub- optimal for gamete maturation in October/November at the Dampier Archipelago.

Secondly, there was a distinct drop in mean monthly wind speed during October and November at the northerly location, whereas wind speed remained relatively constant throughout spring at the Dampier Archipelago (a drop in wind speed occurred only during March). Wind strength is considered to be an important factor influencing spawning time because spawning during a period of slack water is likely to increase fertilisation success (Babcock et al. 1986). Therefore, a distinct period of low winds in October at the Bonaparte Archipelago could be advantageous for spawning during this period.

The data from this study suggests that conditions for reproduction in October/November are more favorable at the Bonaparte Archipelago than at the Dampier Archipelago, however sampling over more years is required to substantiate this. While it is possible that a combination of low SST and relatively strong winds could make conditions less favorable for reproduction in the Dampier Archipelago, additional data over a longer time period together with more detailed comparisons between the two locations is required to elucidate any strong conclusions. The spatio-temporal variability of coral spawning in Western Australia is only just beginning to be revealed, but offers much scope for further research into the factors constraining spawning time.

Sexual Reproduction in the Soft Coral *Lobophytum* sp. in Tung Ping Chau Marine Park, Hong Kong SAR, China

C.W. Yeung[1], P. Ang[1]

[1)] Marine Science Laboratory, The Chinese University of Hong Kong, Hong Kong SAR, China

Abstract. The reproductive biology of soft corals in Hong Kong has never been investigated. The soft coral genus *Lobophytum* is a carpet-like encrusting coral and is commonly found in Tung Ping Chau Marine Park, Hong Kong SAR. Three samples from five marked *Lobophytum* sp. aggregations were collected monthly from 16 Aug 2006 to 7 Jul 2007. Histological sections of each sample were prepared and their gonadal development was observed under the microscope. From the histological analysis of the samples, all colonies bore only eggs. As *Lobophytum* was reported to be gonochoric, all the colonies sampled were therefore female. Male colonies may be missed during sampling. Oocytes from the samples measured increased in mean (±SD) diameter from 116.5±18.8 μm in Aug 2006 to 239.3±82.2 μm in Jun 2007, and dropped back to 93.0±23.2 μm in Jul 2007. This indicates that spawning of *Lobophytum* probably occurred in or before Jul 2007. The oocyte development appeared synchronized as shown in the simultaneous increase in their sizes. However, new oocytes likely developed before the release of the mature ones so that each cycle of development took more than one year to complete. Additional samples will be processed in order to confirm this initial observation.

Key words: *Lobophytum*, Reproductive Biology, soft coral, Hong Kong SAR, .

Introduction

Soft corals are one of the major components in coral reef worldwide aside from hard corals. They can increase the spatial heterogeneity in the reefs, which provide shelter to many other organisms (Jordan-Dahlgren 2002). Soft corals are rich in natural products (Blunt et al. 2005). They can protect and attack their neighbors and their bioactive compounds can be extracted for pharmaceutical and antifouling use. The structure of cemented large sclerites, called spiculite, at the basal part of *Sinularia polydactyla* can also contribute to reef-building (Schuhmacher 1997). Therefore, conservation of soft coral is an important issue, and studying its reproductive biology is one of the major steps to better understand its biology.

There are 29 species in 14 genera of soft corals in Hong Kong. They are mainly found in water from 3 to 20 m depth (Lee 2007). The number of investigations on soft corals in Hong Kong was limited. Previous studies examined their terpenoid contents (Zhang et al 1997; Zhang 2001), associated bacterial communities (Harder et al 2003; Dobretsov and Quan 2003) and distributions (Clark 1997; Fabricius and McCorry 2005; Lee 2007). No information on soft coral reproductive biology was available in Hong Kong.

The living range of soft corals is very wide. They are found from tropical to temperate regions and even in the poles, as well as from shallow water down to the deep sea (Fabricius and Alderslade 2001). There are very few studies about the biology and ecology of soft corals in the sub-tropical region, where Hong Kong is located. Having quite a high diversity of soft corals in such a small place like Hong Kong, it is worthy to investigate Hong Kong soft corals to help fill the information gap in this region.

The reproductive biology of the soft coral *Lobophytum* was the focus of this study. There were some previous studies on *Lobophytum* reproduction in Japan, Australia and Taiwan (Yamazato et al. 1981; Michalek-Wagner and Willis 2001; Fan et al. 2005). Such being the case, the results in this experiment can be compared with those from the other areas in order to help us understand more about the potential inducing factor of spawning in soft corals. This project also provided baseline information about the reproductive cycle of soft corals in Hong Kong, which is essential for their conservation.

Material and Methods

Site and species descriptions

The study site, Lung Lok Shui, is located in Tung Ping Chau Marine Park, Hong Kong SAR. Tung Ping Chau is a relatively remote island in NE Hong Kong. It was designated as a marine park in 2001 to protect the high richness of coral communities around the

island (Lee 2007). On the Northeastern side of Tung Ping Chau Marine Park, the shore is sheltered so that hard corals are abundant. In contrast, the southeastern side is more exposed such that soft corals and gorgonians are more common. Nine species of soft corals were found in Lung Lok Shui (Lee 2007).

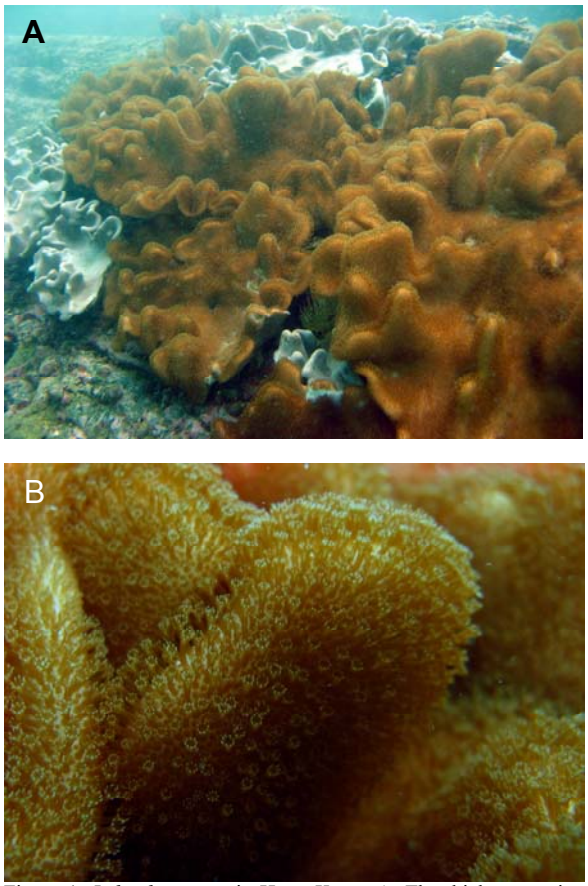

Figure 1: *Lobophytum*.sp. in Hong Kong: **A.** The thick-encrusting capitulum with lobes is yellowish-brown in color. **B.** Closed-up of capitulum showing the dimorphic polyps, in which only the autozooids bear gonads.

The genus *Lobophytum* is low-encrusting with a capitulum which bears polyps above its stalk (Verseveldt 1983). *Lobophytum* sp. is one of the most commonly found soft corals in Tung Ping Chau Marine Park. It is thick-encrusting with lobes and is yellowish-brown in color (Fig. 1). Being a zooxanthellate coral, it grows in shallower water, i.e., 6-11 m in Lung Lok Shui (Lee 2007). Sexual and asexual fissions were reported in *Lobophytum* (Fan et al 2005). It has dimorphic polyps, in which only autozooids but not siphonozooids bear gonads. They were reported to be gonochoric broadcaster (Yamazato et al 1981). Due to its relatively high abundance in the Marine Park, *Lobophytum* sp. was chosen to be the first soft coral in Hong Kong to be examined for its reproductive biology.

Collection and processing of the samples

Monthly sampling was done on *Lobophytum* aggregations in Lung Lok Shui. Five aggregations of *Lobophytum* were located in the site at 5-7 m depth. Assuming the colonies in the same aggregation to be derived from fission of a single colony, three small samples were cut from each aggregation each time. The samples were fixed in 10% formalin for 1 week and preserved in 75% ethanol afterwards. They were then decalcified and mounted in paraffin wax blocks. Thereafter, 7 μm thick microtome sections were prepared for gonad examination. Hematoxylin and eosin were applied to stain the samples.

The sections mounted on slides were observed under light microscope. Photos were taken for the six largest oocytes in each sample. Their longest diameter and the corresponding perpendicular diameter were measured using a computer program Image-Pro Plus 5.0©. The geometric diameter of each oocyte was calculated by the square root of the product of the two diameters. The monthly variation in the oocyte size was plotted with temperature to investigate if the spawning time is correlated with the temperature increase in summer.

Results

Only female gonads were found in the samples (Fig. 2a). This did not contradict with the previous reports that *Lobophytum* is gonochoric (Michalek-Wagner and Willis 2001), yet could not be supported by this result firmly. No planulae were observed in the coelenteron of the samples investigated. Therefore, *Lobophytum* sp. in Hong Kong should be a broadcaster. This is consistent with the previous studies on *Lobophytum* reported in other places.

The color of the oocytes changed from white to pale yellow as they matured (Fig. 2b). The oocyte sizes increased from 116.5±18.8 μm in Aug 2006 to 239.3±82.2 μm in Jun 2007, and dropped back to 93.0±23.2 μm in Jul 2007 as shown in Fig. 3 Corresponding water temperature in each sampling date plotted in the same figure illustrates the relationship between temperature and gonadal development. Spawning likely occurred between June and July 2007, at a time when the water temperature was possibly the highest in the year.

Discussion

Spawning of *Lobophytum* sp. in Hong Kong likely occurred in Jun-Jul 2007. Long day-light and high seawater temperature in summer may be the inducing factors for *Lobophytum* sp. to spawn. Previous studies on the reproductive biology of *Lobophytum* in other areas showed the spawning period to be in July to September for *L. pauciflorum* in Nanwan Bay, Taiwan (Fan et al. 2005), June for *L. crassum* in

Okinawa, Japan (Yamazato et al. 1981), and November for *L. compactum* and *L. crassum* in the Great Barrier Reef, Australia (Bowden et al. 1985; Michalek-Wagner and Willis 2001). All these reported spawning events worldwide occurred during summer and were probably related to the longer day-light time and/or the higher water temperature in this period. It may be an adaptive feature for the genus *Lobophytum* to spawn during summer. Warmer water temperature in summer may be more favorable for increasing the survivorship of the recruiting new coral larvae.

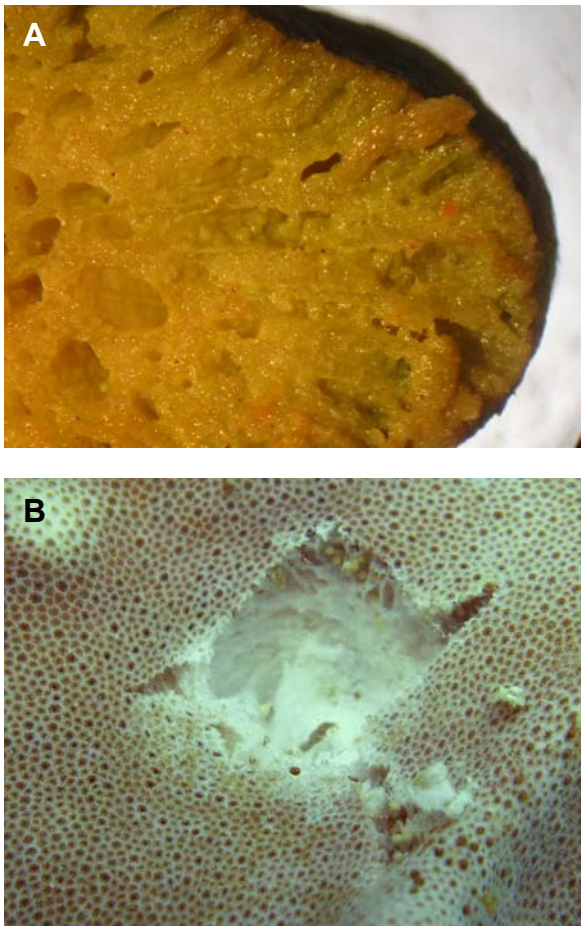

Figure 2: **A.** Section of the capitulum showing the female gonads and eggs. **B.** Color of the oocytes changed from white to pale yellow as they became mature.

Studies on reproduction pattern of hard corals in Hong Kong showed that *Platygyra acuta* (as *P. sinensis*) spawned in May (Liu and Ang 2002), *Favia speciosa* and *Favites abdita* in May-June, and *Leptastrea purpurea* in June-July (Lin 2003). All of these investigated hard corals also spawned in summer. The synchronized pattern of oocyte development of these soft and hard corals in Hong Kong appears to be under the control of these similar factors. Hong Kong is located near the northern limit of coral distribution. Low water temperature in winter (14°C) is not favorable for coral growth. It is thus likely that most soft and hard corals have adapted to spawn in summer to avoid the cold winter water temperature which may also be unfavorable for the early development of their recruits. More investigations are needed to confirm that this is indeed the general trend for other soft coral species in Hong Kong.

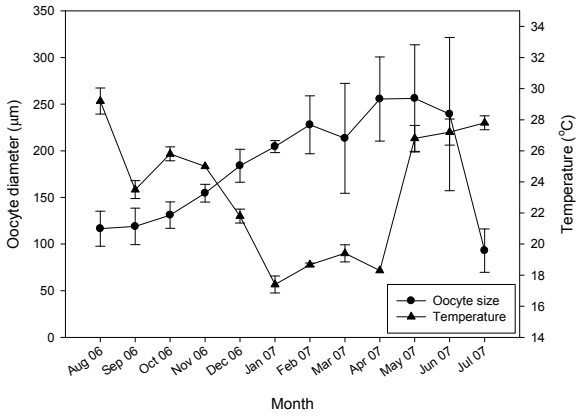

Figure 3: Changes in the mean size (±SD) of the oocyte over the sampling period. The corresponding mean (±SD) seawater temperature at each sampling date is also shown. Spawning of *Lobophytum* sp. likely occurred in Jun-Jul 2007.

The aggregations of *Lobophytum* sp. in Lung Lok Shui were sparsely distributed although there were plenty of uncolonized spaces in the substratum. In our study, only female colonies were found in this site. We hypothesize that some of these aggregated colonies were recruited from outside larval sources at the beginning, but the absence of male colonies would not allow more sexual recruits to be produced. Hence, there was no subsequent colonization of these free spaces by new recruitment. Asexual reproduction by fragmentation or fission becomes more important in forming separate dense aggregations to colonize the surrounding space. This hypothesis remains to be tested while we continue to search for the presence of male colonies in Lung Lok Shui as well as in other surrounding areas.

Abstract. In this study, the lunar periodicity of larval release and development of larvae of *Pocillopora damicornis* in the Gulf of Thailand were investigated. Ten colonies of *P. damicornis*, approximately 15 cm in diameter, were tagged and collected for observation every month. To observe the releasing period of larvae, each colony was placed in a separate tank in a rearing system until the planula larvae were released. The results showed that *P. damicornis* released planulae during the day and night between 1-14 days after the new moon. However, the highest numbers of planula larvae were released 5-6 days after the new moon. The releasing rates were 0.19±0.05 larvae per polyp. Moreover, some colonies released larvae for up to 3 months consecutively. The newly released larvae were approximately 1 mm in length. The larvae started settling on a substrate within 0.5 hours after released, and depressed their body shape in 1.5 hours. The polyp, tentacle, and exoskeleton were observed after 40 hours. After 4 days, a juvenile coral (primary polyp) started budding and expanding its size. At the 6th month, the colony shape started uplifting.

Key words: *Pocillopora damicornis*, coral, lunar periodicity, larval release, larval development

Introduction

Pocillopora damicornis is typically a hermaphroditic brooder releasing the planula larvae with symbiotic zooxanthellae (Szmant 1986). However, in some areas such as Eastern Pacific, this species is a broadcast spawner (Glynn et al. 1991). Releasing periods are related to lunar cycle, which can vary in different areas (Harriott 1983; Richmond and Jokiel 1984; Chou and Quek 1993; Fan et al. 2002). For example, in Singapore, larvae of *P. damicornis* were released from a few days before the new moon to almost the first quarter (Chou and Quek 1993). In Southern Taiwan, larvae were released from lunar days 2-9 (Fan et al. 2002). After released, planula larvae of other pocilloporids settle rapidly on substrates (Baird and Morse 2004). They change their body shape, generate hard structures as a basal plate, and start budding after settling 3-7 days (Sato 1985; Babcock et al. 2003).

Although there are many papers on lunar periodicity and development of *P. damicornis*, some are contradictory in releasing periods, and none of them are from Thailand (Harriott 1983; Richmond and Jokiel 1984; Sato 1985; Chou and Quek 1993; Fan et al. 2002; Babcock et al. 2003; Baird and Morse 2004). The purpose of this study is to investigate the larval releasing period and development of *P. damicornis* in Thailand. The releasing rate and settlement behavior of larvae are also observed.

Materials and Methods

To observe the releasing period of larvae of *P. damicornis*, 10 colonies (each colony 15 cm in diameter) were randomly collected at Khao Maa Cho, Ko Pla Muk and Ko Samae San in Sattahip area, Chonburi Province (Fig. 1). Then, they were tagged and brought back to the laboratory to observe during the full moon and new moon of each month from March 2006 to December 2007. In the laboratory, each colony was placed in a separate tank in a rearing system until the planula larvae were released. To determine numbers of releasing larvae, the larvae were collected from each tank using a Pasteur pipette, and counted every day from the beginning to the end of the releasing periods.

In addition, the releasing larval rates were investigated. Three fragments of corals approximately 3-4 cm in length were randomly cut from each of 5 colonies. Then, the numbers of releasing larvae were counted in each fragment. Each fragment was further decalcified using formic acid solution and sodium citrate to determine the numbers of polyps. Then, numbers of released larvae were compared on a polyp basis.

After the larvae settled, their development stages were observed under the stereo-light microscope. The behavior during the settlement and metamorphosis were also observed.

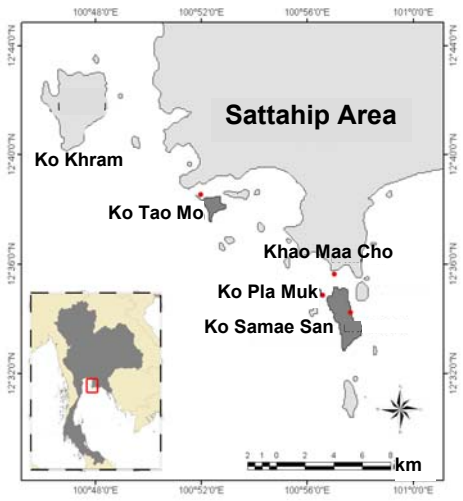

Figure 1: Study sites at Khao Maa Cho, Ko Pla Muk and Ko Samae San, Chonburi Province, where *P. damicornis* was collected

Results

Planulae size of *P. damicornis* was approximately 1 mm. Planulae were released almost every month during 1-14 days after the new moon (Fig. 2). However, the peak of larval release occurred 5-6 days after the new moon. The average numbers of larvae released ranged between 107.2-457.2 individuals per colony per day (Fig. 3). Larvae of *P. damicornis* were found every month. The average numbers of larvae released was high in September 2006 and May 2007. However, when using statistical analyses, there was no significant difference in the numbers of larvae released between months (p>0.05). In addition, the results showed that some colonies could release planulae for up to 3 months consecutively. However, other colonies released planulae every other month. From the observation and calculation, the rate of releasing *P. damicornis* larvae was 0.19±0.05 individuals per polyp.

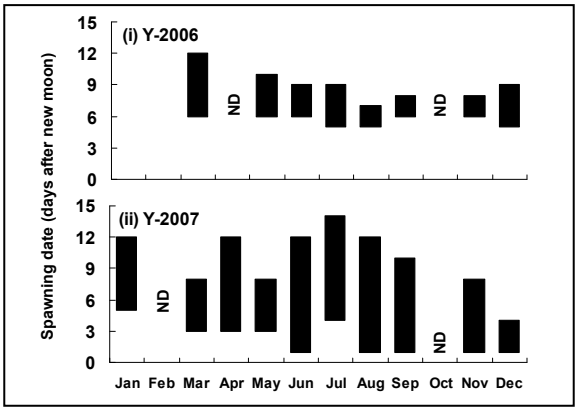

Figure 2: Releasing periods of *P. damicornis* larvae related to lunar cycle during March 2006 to December 2007 (ND: no observation)

After released, the larvae started settling within 0.5 hours. They compressed their body within 1.5 hours, and changed their shape to barrel shape (Fig. 4). During the experiments, larval behaviors were observed. Those behaviors included 1) touching substrates and then swimming (termed touch down), 2) creeping on surfaces of substrates, and 3) spinning while touching substrates. The metamorphosis of *P. damicornis* larvae was shown in Fig. 4. Within 20 hours, their exoskeletons fused to the substratum. The polyp, tentacle, and exoskeleton were observed after 40 hours. A primary polyp started budding to several new polyps 4 days after settling.

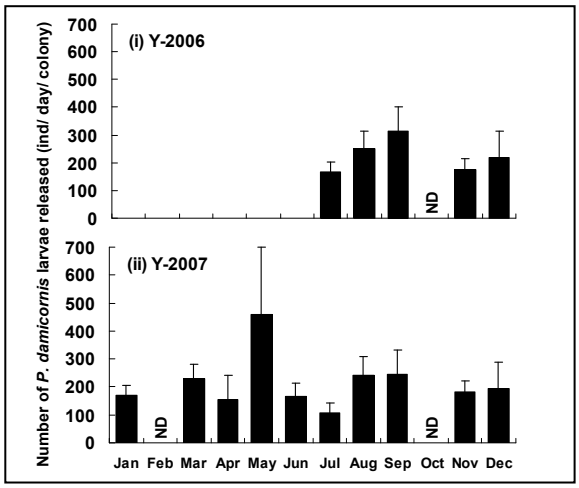

Figure 3: Average number (± SE; n=10) of *P. damicornis* larvae released daily during July 2006 to December 2007 (colony size: 15 cm in diameter) (ND: no observation)

Discussion

In this study, *P. damicornis* in Thailand was found to release planulae during the day and night between 1-14 days after the new moon. In Taiwan and Australia, the releasing periods of *P. damicornis* larvae were between 2-9 and 1-15 days after the new moon respectively (Richmond and Hunter 1990; Fan et al. 2002), while in Singapore, it was between a few days before the new moon to almost the first quarter (Chou and Quek 1993). In agreement with other study (Hodgson 1985), *P. damicornis* in Thailand also released both during the day and at night. From the observation, there was no difference in the numbers of larvae released between months (p>0.05). The results also showed that planulae were present every month. In Heron Island, Australia, Tanner (1996) reported that *P. damicornis* larvae were observed during summer months (between September to April), but were rarely present during the winter. Harriott (1983) showed that the reproduction of *P. damicornis* was not synchronized within a colony due to different stages of gonad maturation in different polyps. Thus, every polyp in a colony may not release larvae during

a certain reproductive cycle (Harriott 1983). In addition, Fadlallah (1983) suggested that in *P. damicornis,* testes matured before ovaries to avoid self-fertilization, which led to asynchronization in a colony.

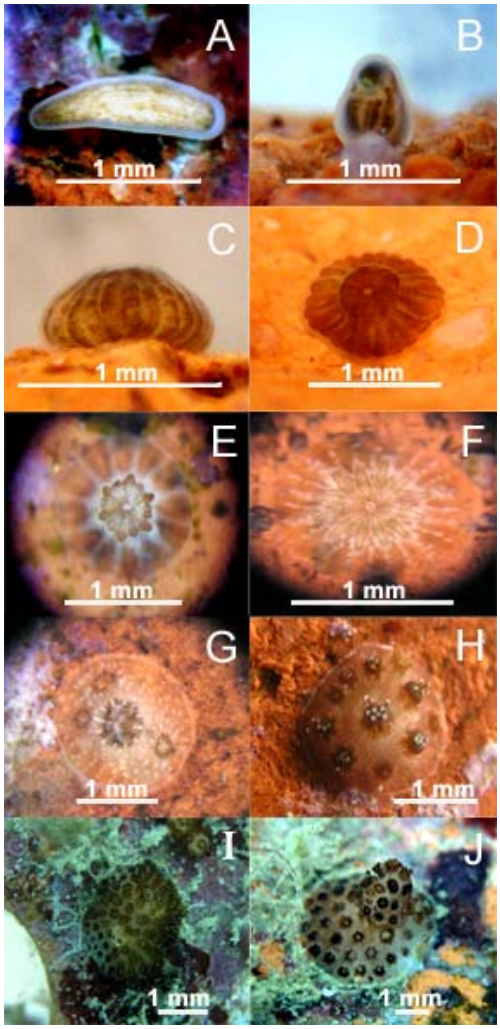

Figure 4: Metamorphosis of *P. damicornis*. A) searching for suitable plate; B) started attaching, 0.5 hrs; C) depressed its shape, 1.5 hrs; D) polyp formation, 5 hrs; E) tentacles and exoskeleton formation, 20 hrs; F) tentacles and exoskeleton observed, 40 hrs; G) started budding, 4 days; H) 1 month old; I) size expanding, 3 months old; J) started uplifting, 6 months old.

The rate of larval release can vary depending on colony sizes (Tioho et al. 2001). In this study, rate of releasing *P. damicornis* larvae was 0.19±0.05 individuals per polyp per month. Tanner (1996) showed that *P. damicornis* in Heron Island, Australia released 1-3 larvae per polyp, and in each month, only 1/3-1/2 of all polyps in a colony released planulae.

The settlement behaviors and development of larvae observed in this study were similar to other previous studies (Sato 1985; Babcock et al. 2003; Baird and Morse, 2004). Once larvae settled, metamorphosis was started and basal plate was formed. *P. damicornis* started budding 3-7 days after the settlement (Sato 1985).

In conclusion, lunar periodicity of larval release by *P. damicornis* in Thailand was consistent with those reported in other areas. However, the releasing period in Thailand was longer than that of other areas. More studies are needed to determine what environmental factors can influence the gonad maturation of *P. damicornis* in Thailand.

Light sensing and the coordination of coral broadcast spawning behavior

P.D. Vize, J.D. Hilton, A.K. Brady, S.W. Davies

Department of Biological Sciences, University of Calgary, 2500 University Drive NW, Calgary, Alberta, T2N1N4, Canada

Abstract. In the Caribbean and Gulf of Mexico hermatypic corals undergo mass spawning on just one or two nights per year, peaking on the eighth evening after the August full moon. This event occurs with extraordinary consistency and is predictable to within a few minutes from year to year. Corals use the moon to determine the date of spawning and sunset time to set the hour and minute of gamete release. We have been exploring whether these two parameters entrain biological rhythms or whether corals respond directly to environmental signals. The literature supports a potential role for entrained circalunar systems setting the spawn date and for non-entrained direct responses to light setting the spawn time but neither has been conclusively demonstrated to date. We propose that G-protein coupled photoreceptors modulate second messenger levels in the cytoplasm and that these in turn lead to changes in protein abundance or protein phosphorylation patterns which then control spawning behavior. In support of this hypothesis we have identified dozens of differences in the proteome of Montastraeacavernosatissue dependent on light. We are using these molecular markers to dissect the cellular basis of lunar and solar light responses.

Key words:circadian rhythms, lunar periodicity, broadcast spawning, mass spawning, scleractinian

Introduction

Broadcast spawn timing is regulated by multiple environmental cycles- seasonal, lunar and solar. The first of these, seasonal, sets the month of spawning in each locale. How exactly corals synchronize spawning with seasonal cycles of gonad maturation remains unknown, but it is associated with solar insolation patterns (van Woesik et al. 2006) and periods of calm weather (Hagman et al. 1998). The second environmental parameter important in spawn timing is the lunar cycle, which sets the date of spawning(Babcock et al. 1986). This is clearly illustrated by the accuracy with which spawning dates can be predicted using the lunar calendar. The third parameter is the solar cycle, which sets the hour and minute of spawning (Levitan et al. 2004; Vize et al. 2005). This is clear from the observation that spawn time changes with the time of year and changes in day length and can be predicted to within minutes relative to sunset time from year to year.

Each of these cycles- seasonal, lunar and solar- could directly regulate cellular processes in corals or could act by entraining biological rhythms with annual, lunar or daily periodicities, and the entrained rhythms would then regulate the processes. As little is known about how the month of spawning is set, we will focus on the date and time of broadcast spawning for the remainder of this report. Excellent evidence exists for the presence on circalunar rhythms in reproductive behavior in brooding corals. Planula release by brooders can continue for many months even when the lunar input is blocked or is held constant (Jokiel et al., 1985). Furthermore, monthly cycles of planula release takes months to be reestablished when placed in a lunar phase shifted regimen, once again strong evidence that entrainment is involved (Jokiel et al., 1985). An entrained system would have considerable advantages in keeping spawning dates consistent from year to year as fluctuations in weather, cloud cover etc. would have minimal effects on timing.

While corals display some circadian rhythms with a periodicity of around 24 hours (Sweeney, 1976) these do not appear to regulate the time of spawn release. When sunset time is artificially moved forward on the day of spawning, spawn release occurs in a correspondingly early manner (Knowlton et al., 1997; Levitan et al., 2004), which would not happen if an entrained system regulated this process. This indicates that either light directly inhibits or darkness directly promotes spawning behavior. Species species that spawn in different time windows must have different thresholds for a common light regulated factor (e.g., a second messenger) or the factor changes at different rates in different species. By determining what signal transduction pathways

are involved and what second messengers they use will allow us to uncover how corals perceive light and to understand the molecular control of coral spawning behavior.

Material and Methods

Spawning observations

The documentation of spawning times at the Flower Garden Banks, northwest Gulf of Mexico, have been made by our research group for the past 12 seasons. The detailed observations from 1997-2003 were compiled in a recent report (Vize et al., 2005) and are also summarized below. Common species at the FGB that were surveyed include: Colpophyllianatans (6%), Diploriastrigosa (13%), Montastraeaannularis (<6%), M. cavernosa (13%), M. faveolata (9%), M. franksi (37%) and Stephanocoeniaintersepta (<6%), where the percentage of live coral cover indicated in brackets if it is known (Pattengill-Semens and Gittings, 2003).

Tissue sampling

Fragments were collected from a single M.cavernosa colony at noon and kept on deck in a bucket of seawater along with an air-stone and illuminated by ambient light. Tissue was collected from coral fragments by scraping the surface layer into a test tube containing a commercial protein preservation buffer (phosphosafe- Novagen). A second sample was treated in an identical manner but harvested 4.25 hours post-sunset (midnight).

Protein analysis

Proteins were visualized by 2D electrophoresis followed by silver staining using standard protocols Marengo et al., 2008). The first dimension was a pH 3 – 10 IEF gradient and the second dimension by molecular weight (10% polyacrylamide).

Results

Spawn timing

Observations of spawn timing were made by the same group of divers each year. This was found to greatly increase the consistency of spawn timing reports (Vize et al., 2005). Spawn times for each of the six common species that broadcast spawn on the eighth evening after the August full moon are shown in Fig.1. Spawning windows for each species are approximately 30 minutes in length except for D.strigosa, which is due to a slow tailing off in spawning activity in this coral. However, like other species, the peak of D. strigosa spawning also lasts for around 30 minutes. Fig.1 also highlights the unique time windows in which each species spawns, once again with the single notable exception of D.strigosa.

In both gonochoric species surveyed the males colonies begin to release sperm approximately 20 minutes prior to the time at which females begin to expel eggs. We have hypothesized that while females may be primed and ready to release via similar timing processes as males, sperm may act as the ultimate trigger of egg release(Hagman et al., 1998). In the case of the common and large species, M.cavernosa, females spawn for approximately 30 minutes. For the less common and much smaller species S. intersepta, spawning is much briefer and females all release within a window lasting only about 10 minutes.

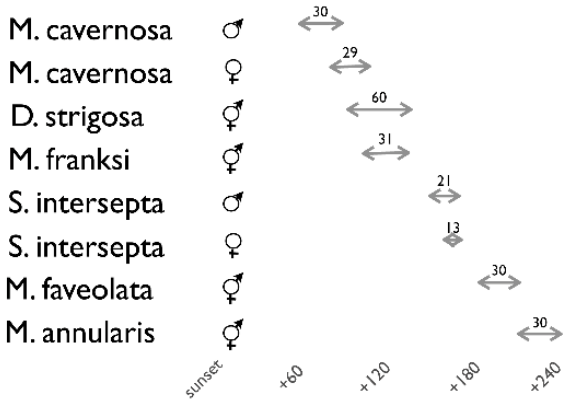

Figure1: FGB spawn times relative to sunset. The number above the arrow indicates the length of the spawning window in minutes. Time after sunset is indicated on the X axis.

This pattern is extremely consistent from season to season. Figure 2 shows the average start and stop times for each species, averaged over eight spawning events, plus the variance over the eight seasons. Of the 16 times noted, 10 are consistent to within 15 minutes over all eight seasons, and 8 consistent to less than 10 minutes.

		start	+/-	stop	+/-
M. cavernosa	♂	1:01	4	1:31	13
M. cavernosa	♀	1:27	23	1:56	9
D. strigosa	☿	1:29	21	2:29	21
M. franksi	☿	1:51	16	2:20	19
S. intersepta	♂	2:38	13	2:59	7
S. intersepta	♀	2:46	10	2:59	7
M. faveolata	☿	3:13	7	3:43	7
M. annularis	☿	3:42	6	4:12	6

Figure 2: Seasonal consistency in coral spawning times. The average time at which coral spawning begins, along with the variation from the average for each species/sex is indicated.

The number of individual corals spawning in any particular season varies quite widely at this location.

Light sensing

Other invertebrates sense light via opsin and rhodopsin visual photoreceptors and non-visual melanopsins (Terakita et al., 2005). In all cases the photoreceptors act via trimeric G-proteins and regulate levels of a soluble second messenger within the cytoplasm of the light-responsive cell (Rayer et al., 1990). If the temporal precision of coral spawn timing is regulated by the same system, as it is likely to be, light may act by upregulating a second messenger that is an inhibitor of spawning or darkness may allow the accumulation of a second messenger that activates spawning. In bothscenarios the altered second messenger levels will lead to changes in protein phosphorylation patterns and the changes in protein activity caused by these changes could trigger spawning. Similar universal systems regulate cellular processes in examples ranging from bacterial chemotaxis to human neurobiology and are direct cellular responses to environmental stimuli (Bourne, 2006).An alternative to this class of processes is entrained biological rhythms (Fig.3)(Dunlap et al., 2004). While light still acts on cells in the same manner and causes changes in second messengers and protein phosphorylation, these changes entrain biological clocks over a period of time. An entrained clock could then accurately regulate cellular processes even when the entraining stimulus is removed (Dunlap et al., 2004).

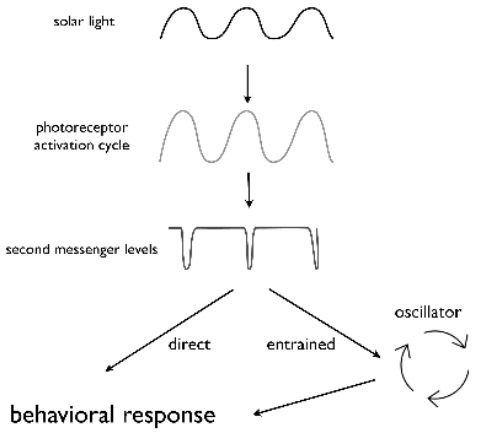

Figure 3: Coral timing may be directly controlled by environmental signals or it may be indirectly regulated by an entrained biological rhythm.

If the spawning response is direct, changes in second messenger levels will control spawn timing while if an entrained clock regulates spawning the key molecules may be regulated at the transcriptional or protein stability levels. There is considerable overlap between these options, but in each case a different set of mediators is actually regulating the biological process.

We have initiated an analysis of changes in protein abundance associated with changes in

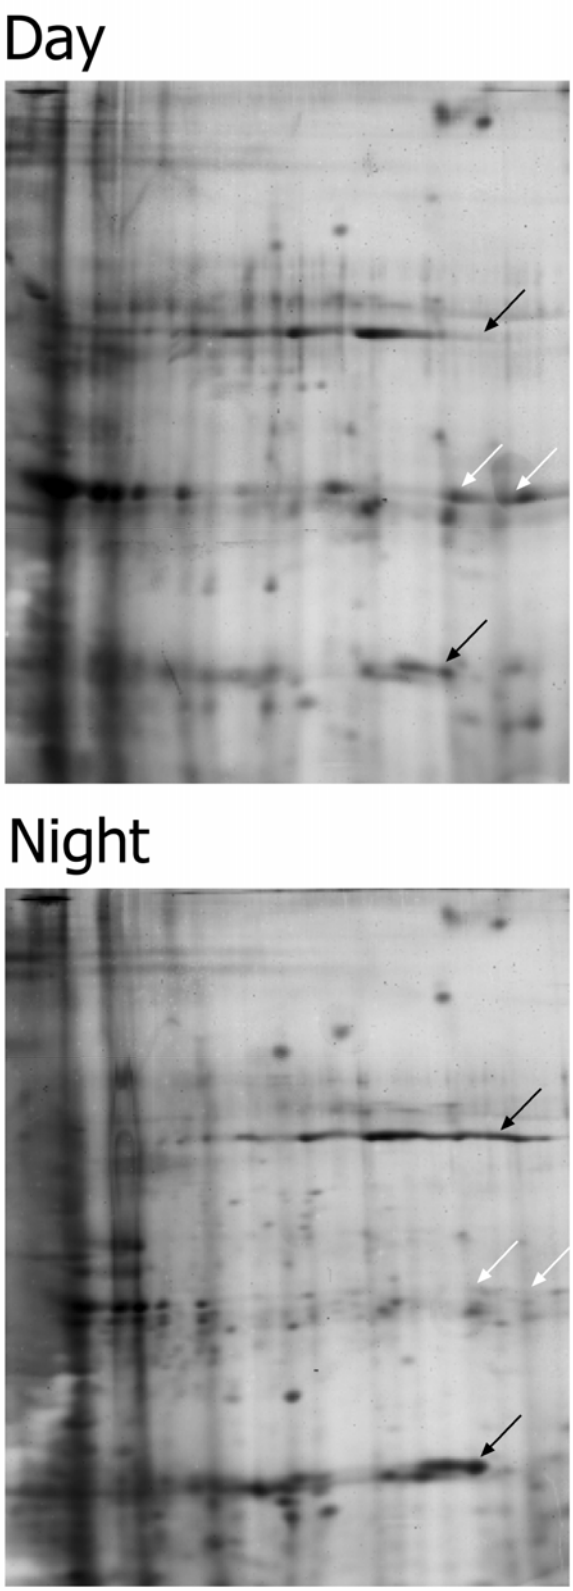

Figure 4: Proteomic analysis of coral tissue harvested in the day or at night. White arrows indicate examples of proteins more abundant in the day samples and black arrows indicate proteins more abundant in darkness. IEF in dimension 1 was from 3 (left) to 10 (right). Molecular weight runs from high (top) to low (bottom).

coralillumination using 2D electrophoresis. Preliminary analysis indicates that dozens of proteins differ in the proteome in M. cavernosa under different lighting conditions (Fig.4).

Discussion

Caribbean corals display extraordinarily consistent spawning behavior, varying by only a few minutes in the time at which they begin and end spawning from season to season. Evidence in the literature implicates circalunar systems as playing a central role in regulating the date of spawning (Jokiel et al., 1985), but the system controlling the time of spawning appears to be a direct response to the environment (Knowlton et al., 1997). However, definitive evidence for direct versus entrained regulation of spawning time and date has not been generated.

Analysis of proteins from the same individual coral collected at midday or midnight indicates that there are many differences in the proteome over this time. As this analysis was performed on whole tissue homogenates containing both coral cells and zooxanthallae, identified proteins could belong to either organism, or to other symbiotic microorganisms. However, as the vast bulk of the protein is from coral cells these are the most likely to be visualized by silver staining.

Although the identity of the proteins that change in abundance from day to night is not known, these can be used to test many aspects of coral responses to light. For example, if a protein is present in the day sample but not the night sample, we can test whether this change still occurs if coral tissue is kept under constant illumination or constant darkness. If it continues to cycle when environmental parameters are constant this must be due to an entrained biological clock, while if it remains constant under constant conditions, it must be directly regulated. We can also test whether pharmacological agents that stimulate or block specific signal transduction pathways can convert light type protein patterns to dark type, and visa versa. Finally, protein gels such as these can be transferred to membranes and probed with phosphospecific antibodies to study changes in the phosphoproteome, determine if these are entrained or direct, and whether they respond to signal transduction pathway changes. This course of experiments will allow us to determine the biochemical basis of the temporal regulation of coral spawning behavior.

Abstract
Coral bleaching related to climate change is one of the major threats to coral reefs today. This study examines bleaching responses of scleractinian corals at four Kenyan sites (Kanamai, Vipingo, Mombasa and Nyali) representing shallower and deeper lagoon habitats. Bleaching incidence was monitored for the whole coral community, while zooxanthella densities and chlorophyll levels were monitored for selected species (*Pocillopora damicornis*, *Porites lutea* and *Porites cylindrica*) during non-bleaching and mild-bleaching years. The objective was to determine whether corals in different habitats display varying resistance and resilience to bleaching and to indicate which habitat characteristics are responsible. Differences in bleaching responses between shallower and deeper lagoons were observed, with shallower sites Kanamai and Vipingo exhibiting lower bleaching incidence than deeper sites Nyali and Mombasa. Shallower lagoons also displayed higher fluctuations in light and temperature than deeper sites, with higher maximums, lower minimums, higher standard deviations and higher diel variation. This suggests that corals in the shallower lagoons have acclimatized to become more resistant to bleaching because of the fluctuating conditions they endure daily. In sites with higher bleaching incidence, it was found that coral recovery occurred more quickly in the protected area (Mombasa) compared to the reserve (Nyali).

Keywords
Coral bleaching, coral acclimatization, resilience, Kenya

Introduction

Coral colonies have been observed to acclimatize or adapt to fluctuating temperature and irradiance levels, and this prior experience might make the colonies more able to resist unexpected bleaching events (Brown et al. 2002a, Brown et al. 2002b). Acclimatization can be defined as the ability of an organism to undergo phenotypic changes in response to stress in the natural environment that result in the readjustment of the organism's resistance levels to that stress (Coles and Brown 2003). Adaptation occurs over the long-term when the more stenotopic members of a population are eliminated by environmental stress, leaving the more resistant organisms to reproduce and recruit to available habitat (Coles and Brown 2003). Threshold temperatures that induce coral bleaching-related mortality vary worldwide due to selective adaptation and according to the maximum water temperatures that are normal in the area, implying a capacity of corals and/or zooxanthellae to survive higher temperatures for a certain period of time. Furthermore, corals that are regularly exposed to stressful environmental conditions have been shown to acclimatize and exhibit physiological resistance to elevated temperatures and UV-radiation that exceed normal thresholds (Brown et al. 2000; Brown et al. 2002a; Brown et al. 2002b, Coles and Brown 2003).

In order to combat the worst effects of climate change and to conserve this valuable ecosystem, it is important to determine which factors affect coral reef bleaching resistance and resilience and to apply this knowledge in management plans. Although bleaching events cannot be prevented by managers, by implementing appropriate management responses it is possible to help a coral reef recover from bleaching and to mitigate the worst effects.

This study examines the bleaching responses of corals at four sites (Nyali, Mombasa Marine Park, Kanamai and Vipingo) representing two distinct lagoon habitats on the Kenyan coast (deeper and shallower lagoons). The sites were characterized using environmental parameters such as depth, water flow, light and temperature. Bleaching responses were monitored for the general coral community and zooxanthella densities and chlorophyll levels were monitored for target species (*Pocillopora damicornis*, *Porites lutea* and *Porites cylindrica*)

during a non-bleaching year (2006) and a mild bleaching year (2007). The objective of this study is thus to determine whether corals in different habitats display different bleaching responses (i.e. resistance and resilience) and to indicate which environmental characteristics are responsible for the variation in response.

Materials and Methods

Five large and healthy coral colonies for each target species (*Pocillopora damicornis*, *Porites cylindrica* and *Porites lutea*) were mapped in two shallower lagoons (Kanamai and Vipingo, 0.4 m depth and 0.6 m at low tide respectively) and two deeper lagoons (Mombasa Marine Park and Nyali, 1.4 m and 1.8 m depth at low tide respectively) along the Kenyan coast. Target species were chosen according to general abundance and bleaching susceptibility, with one highly susceptible (*Pocillopora damicornis*), one moderately susceptible (*Porites cylindrica*) and one resistant (*Porites lutea*) target species. Coral size class and line intercept transect data were also collected for two fixed 25x2 m transects at each site.

The bleaching season in Kenya occurs during the late northeast monsoon from mid March when doldrum conditions become most intense to late April when the first storms of the southeast monsoon induce cooling of surface waters. In the two years of the study, sampling began before bleaching during the northeast monsoon (February and early March), continued during bleaching season of the northeast monsoon (late March and April) and finished during the recovery period of the southeast monsoon (May, June and July).

Coral fragments were collected from the mapped colonies using a hammer and chisel. The fragments were transported to the laboratory submerged in seawater in small plastic bottles and were held in an aerated seawater tank for less than 24 hours. Coral tissue was removed from the skeleton using a water jet. Seawater was then added to the tissue to make up a fixed volume of 500 ml. The tissue slurry was homogenised using a hand-held homogenizer and 1.0 ml of homogenate was loaded into a Sedgwick-Rafter chamber. Using a compound binocular microscope and a magnification of x400, the number of zooxanthellae in 10 random quadrats was recorded. The counting chamber was then reloaded and another 10 random quadrats were counted. The area of the coral skeleton was measured using the aluminium foil method (Marsh 1970); the area/weight ratio of aluminium foil was determined and coral skeletons were then wrapped in this foil. The foil was then trimmed to fit the skeleton area and weighed. Using the weight of the trimmed foil and the area/weight ration for the foil, the skeleton area could be determined.

To measure chlorophyll *a* levels, a known volume of the homogenate was filtered through a GF/F filter paper and the filtrate was dissolved in 10 ml of 90% acetone. It was then centrifuged for 10 minutes at 2000 rpm and the chlorophyll absorbance was read using a Whatman spectrophotometer.

If it was observed, bleaching incidence was recorded in the water using a random swim method. This consists of noting the size class, genus and bleached/pale/dead percentages of each bleached colony in 20 haphazard 2 m^2 areas at each site.

Water temperature was monitored using underwater Hobo temperature loggers that were left at each site during the entire duration of the study. Light was monitored using a Hobo light meter for only 24-hour periods on the same day and time at each site to avoid theft and overgrowth of the light meter. Water flow was measured using a clod card method (McClanahan et al. 2005). Plaster-of-Paris clod cards were made in an ice-cube tray, dried and weighed before being deployed in the field in small net bags that were tied to the substrate. They were collected 24 hours later, dried and weighed again in order to determine how much had dissolved. Current speed in g d^{-1} (24 h) was obtained by dividing weight loss by deployment time. Weight loss [g] was then converted to flow speed (Vw = cm s^{-1}) using the equation $Vw = (DWclod - 0.932)/2.357$, which was obtained by studies of clod dissolution in a flume with controlled water flow (Anzai 2001).

Statistical analyses were performed using the program Minitab (version 10.1). Differences in zooxanthella density were investigated using the Man-Whitney U test with Bonferroni corrections and the Kruskal-Wallis test.

Results

Depth

Nyali and MMP are deeper lagoons (1.8 m depth and 1.4 m depth at mean low tide respectively) while Kanamai and Vipingo are shallower lagoons (0.4 m depth and 0.6 m at mean low tide respectively).

Temperature

The shallower lagoons Kanamai and Vipingo displayed the most fluctuating temperature conditions, with higher standard deviations (±1.9°C and ±1.5°C respectively), higher maximum temperatures (36.2°C and 33.8°C respectively), lower minimum temperatures (24.0°C and 23.7°C respectively) and bigger differences between diurnal and nocturnal temperatures (+0.9°C and +0.4°C respectively) than the deeper lagoons. Between the

two, Kanamai displayed larger fluctuations, as well as the highest average temperature overall (27.8°C) .

The deeper lagoons of MMP and Nyali displayed less pronounced temperature variations with lower standard deviations (both ±1.4°C) as well as smaller maximum-minimum (+8.9°C and +8.1°C respectively) and diurnal-nocturnal (both +0.2°C) differences than the shallower lagoons. However, the deeper lagoons displayed bigger temperature increases from the 2006 to 2007 northeast monsoon bleaching seasons, with a +0.9°C increase in Nyali and a +0.8°C increase in MMP compared to a +0.7°C increase in both Kanamai and Vipingo (fig. 1).

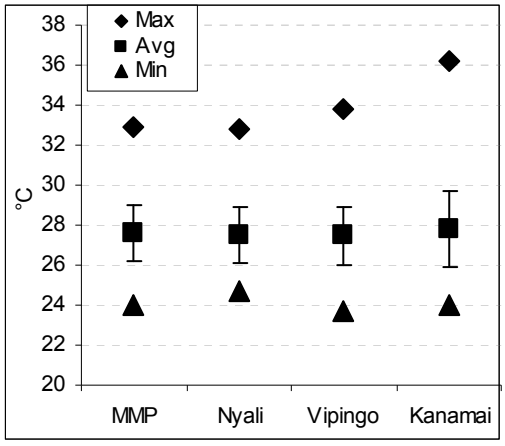

Figure 1.
Average, standard deviation, minimum and maximum temperatures for all sites.

Light

As expected, the shallower lagoons Kanamai and Vipingo also displayed more fluctuating light regimes than the deeper lagoons Kanamai (4913±14,315 lux) and Vipingo (4758±10,489 lux) both displayed much higher average light levels, higher standard deviations and higher maxima (70,846 lux and 110,223 lux respectively) than MMP (average of 518±879 lux, maximum of 5167 lux). Although light data are unavailable for Nyali, it is likely that light levels are similar to MMP given the depth and sediment levels of the site.

Water flow

There was no clear trend between water flow at deeper and shallower lagoons. MMP consistently displayed the highest average water flow during both neap (6.4 cm/s) and spring tide cycles (9.0 cm/s). Kanamai (5.4 cm/s) displayed similar water flow to Nyali (5.5 cm/s) and Vipingo (5.6 cm/s) during neap tide and it appears that MMP stands out as the site displaying highest water flow.

Substrate cover

MMP and Kanamai displayed higher hard coral cover (28.4% and 23.0% respectively) while Nyali and Vipingo displayed lower hard coral cover (14.7% and 10.6% respectively). Macroalgal cover was higher in deeper sites MMP (25.5%) and Nyali (21.0%) than in shallower sites Vipingo (8.3%) and Kanamai (3.7%).

Coral cover

All sites are dominated by massive and branching *Porites* colonies. 90.5% of MMP, 80.3% of Kanamai, 59.9% of Nyali and 42.2% of Vipingo coral cover was massive and branching *Porites.* The highest relative coral cover of the more bleaching-susceptible genera *Acropora* and *Pocillopora* is found in Vipingo (10.2%) and Nyali (8.3%). *Acropora* and *Pocillopora* only accounted for 3.7% of Kanamai's coral cover and 0.7% of MMP's coral cover.

Bleaching and mortality incidence

Bleaching was first observed during late April of 2007. The shallower lagoons Kanamai and Vipingo exhibited lower levels of combined paling, bleaching and mortality (4.4% and 6.3% of total coral area respectively) than the deeper lagoons Nyali and MMP (35.1% and 26.9% of total coral area respectively). During the recovery period, MMP still exhibited relatively high bleaching incidence (9.8%) but low mortality (0.9%). Nyali exhibited the highest mortality (11.7%) and also relatively high bleaching (4.5%). In July, mortality increased to 13.1% in Nyali and 2% in MMP, but bleaching incidence in MMP decreased to 6.0%, indicating recovery (fig. 2).

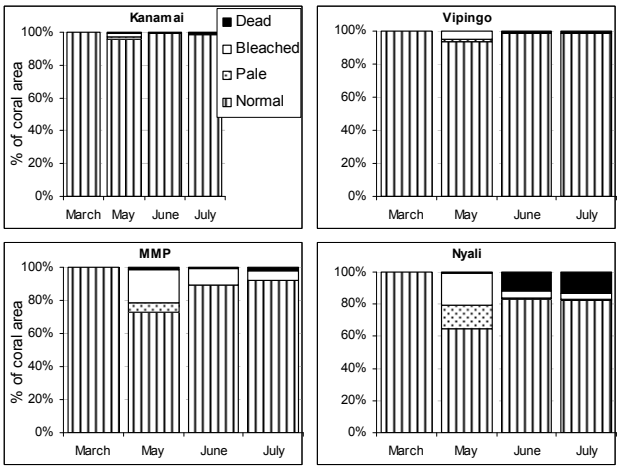

Figure 2. Bleaching and mortality incidence for all for sites from March to July 2007. Nyali and MMP exhibited higher bleaching than Kanamai and Nyali. Corals in MMP recovered better than in Nyali.

Pocillopora and *Porites* accounted for the highest proportion of bleached colonies, but differed greatly

in their mortality rates. In MMP, Nyali and Vipingo, *Pocillopora* accounted for 37%, 47.1% and 33.3% of bleached colonies respectively. In Kanamai, MMP and Nyali, *Porites* accounted for 47.2%, 28.3% and 13.8% of bleached colonies respectively. However, during the recovery period of June and July, *Porites* experienced low bleaching-related mortality while *Pocillopora* experienced highest mortality in all sites (from 37.5% in Vipingo to 90% in MMP). Of the three target species only *Pocillopora damicornis* suffered significant mortality in both 2006 (50% overall mortality) and 2007 (47% overall mortality) with colonies in Kanamai experiencing the lowest mortality rate in both years.

Zooxanthella densities

Average zooxanthella densities for marked colonies (*Pocillopora damicornis*, *Porites lutea* and *Porites cylindrica*) were higher for all species at all sites in 2006 than in 2007 (Man-Whitney U test, $p<0.05$). Average zooxanthella densities were also higher in shallower sites than in deeper sites for all species (Man-Whitney U test $p<0.001$). In general, Kanamai exhibited the highest average zooxanthella densities while MMP displayed the lowest. *Porites lutea* colonies exhibited the highest zooxanthella densities while *Pocillopora damicornis* (Kruskal-Wallis, $p<0.001$).

Chlorophyll a levels

Chlorophyll *a* concentrations were generally higher in shallower than in deeper sites, and Kanamai exhibited the highest chlorophyll *a* concentrations while MMP exhibited the lowest (Man-Whitney U test, $p<0.05$).

Discussion

Considerable differences in bleaching responses between shallower and deeper lagoon sites were observed, with shallower sites Kanamai and Vipingo exhibiting much lower bleaching incidence than deeper sites Nyali and MMP in both haphazard sampling and marked colonies. These results suggest that corals in the shallower lagoons have acclimatized and/or adapted to the more fluctuating environmental conditions they endure on a daily basis and have become more resistant to thermal stress than corals in the deeper lagoons. McClanahan et al (2005) found similar responses and concluded that 'that benign or stable environments will produce communities that are less resilient to rare climatic disturbances but if disturbances are sufficiently infrequent, they will maintain high numbers of species. Variable or stressed environments will maintain dominant organisms capable of withstanding climatic disturbances but will lose those rare members of the community that cannot adapt to the stressful conditions.'

Shallower sites Kanamai and Vipingo displayed more fluctuating temperature and light regimes than deeper sites Nyali and MMP with higher maxima, lower minima, larger standard deviations and larger diel variations. The smaller volumes of water in the shallower lagoons probably explain the difference in temperature and light regimes; shallower lagoons absorb but also lose heat more quickly and attenuate less light than in the deeper lagoons.

Differences in temperature and light regimes could also explain differences in bleaching responses between similar-depth sites. Kanamai displayed lower bleaching incidence and bleaching-related mortality than Vipingo and is also a shallower site with higher average temperatures, standard deviations, differences between maximums and minimums, diel variations, maximum light levels and standard deviation in light levels. Similarly, MMP displayed higher average temperatures and difference between maximum and minimum temperature than Nyali and also suffered lower bleaching incidence,

On the other hand, water flow did not correlate well with bleaching incidence, and although corals in Nyali suffered much higher bleaching incidence than Kanamai and Vipingo, all these sites displayed very similar water flow velocities. It therefore appears that light and temperature histories were more influential than water flow in determining the bleaching responses of corals.

Studies have shown that corals with higher zooxanthella densities are more resistant to bleaching (Grimsditch et al. 2008), a hypothesis that is further confirmed by this study. *Porites lutea* displayed the highest densities and was the most resistant to bleaching. *Porites* colonies made up a large proportion of bleached corals but they exhibited very little mortality. *Pocillopora damicornis* exhibited the lowest densities and was the most susceptible to bleaching, accounting for most bleaching-related mortality in all sites. Zooxanthellae population dynamics could thus partly explain bleaching responses of different genera.

All sites were dominated by massive and branching *Porites* corals, discounting the possibility that large variations in coral community compositions determined bleaching responses. However, differences in community composition could partially explain varying bleaching responses between similar-depth sites. Nyali exhibited higher bleaching incidence than MMP and also a higher proportion of area covered by bleaching-susceptible

genera (i.e. *Pocillopora* and *Acropora*). The same applies to Vipingo compared to Kanamai.

During the recovery period, colonies in Nyali displayed higher mortality than those in MMP, while a higher proportion of corals in MMP remained bleached but did not die. It is possible that colonies in Nyali were being overgrown by algae more quickly than those in MMP, which remained in a bleached state longer. This could be due to the protected status of MMP and that herbivory levels could be higher than in Nyali, which is subject to high fishing pressure. Populations of important herbivores such as parrotfish and surgeonfish have been shown to be significantly higher in protected areas than in non-protected areas along the East African coast (McClanahan and Arthur 2001).

In conclusion, this study shows that during the 2007 bleaching season, corals in the shallower lagoons of Kanamai and Vipingo were more resistant to bleaching stress than corals in the deeper lagoons of MMP and Nyali, probably due to a history of higher light and temperature extremes and variation at the shallower sites. Whether this acclimatization is due to short-term phenotypic changes or due to a longer-term process of adaptation through natural selection is a question that begs further research. *Pocillopora* was the genus most susceptible to mortality and *Porites* displayed high resistance to mortality. Among all these patterns of bleaching susceptibility, it is not clear whether the acclimatization is host-based or symbiont-based, and monitoring of the genetic identity of the zooxanthellae in corals at these sites could help in answering this question. Finally, bleached corals in MMP suffered lower levels of mortality than in Nyali, maybe associated with the possibility that rates of herbivory are higher in MMP due to its protected status. While herbivory is often related to resilience of reefs and the influence of herbivores assisting recovery by coral recruits, this result suggests herbivory may also mediate interactions between algae and bleached corals, and assist in the survival of bleached corals.

Reef resilience and change 1998-2007, Alphonse Atoll, Seychelles

A.B. Hagan, T. Spencer

Cambridge Coastal Research Unit, Department of Geography, University of Cambridge, Cambridge, CB2 3EN, UK

Abstract. Alphonse Atoll, southern Seychelles (7°01'S; 52°44'E), a small (11.28 km^2) atoll with minimal anthropogenic influences, was severely impacted by the Indian Ocean warming event of 1997-1998. Quantitative measurements of benthic cover commenced at this location at the peak of the warming (April 1998). Underwater videography surveys of fixed transect lines were made 2001-2007, providing quantitative information on the changing benthic cover. Immediately post-bleaching, the scleractinian community was dominated by few genera, which rapidly re-colonised bare surfaces, including dead coral skeletons. Lagoon corals and many shallow water corals, presumably acclimatized to warmer water conditions, were resilient to the 1998 thermal stress and may have seeded local coral recovery. In December 2006, wave fields associated with the passage of Cyclone Bondo resulted in transport of *Porites* colonies and large blocks of reef framework onto reef-flats, loss of post-bleaching coral recruits and increased macro algal cover on the fore-reef slope. This location provides one of the most detailed long-term (> 9 yrs) records of post-bleaching reef dynamics in the Western Indian Ocean. It demonstrates i) the interaction between, and subsequent recovery from, both physiological and physical disturbances and ii) varying resilience by atoll environment (fore-reef slope, reef crest, lagoon).

Key words: Western Indian Ocean, coral bleaching, reef recovery, cyclone impact.

Introduction

The major El Niño which started in early 1997, and lasted for 12 months until a rapid switch to La Niña conditions in mid 1998, resulted in severe coral bleaching and bleaching-related mortality world-wide (Wilkinson 2000). The Indian Ocean in particular was severely affected with 'probably the most extensive bleaching ever witnessed' occurring in the central and northern Indian Ocean during the first six months of 1998 (Wilkinson 2000:23), although there were considerable regional differences in the intensity and duration of ocean warming and related bleaching (Spencer et al. 2000; Turner 1999). Individual reefs in the Seychelles suffered between 40-90% coral mortality as a consequence of this bleaching event (Bigot et al. 2000).

From July 1997 to July 1998, mean monthly sea surface temperature for the Seychelles showed a marked divergence from the long-term trend (1961-1997) (Spencer et al. 2000). Sea surface temperature remained above 30°C for three months, until April 1998, and an anomaly of nearly 2°C was recorded during February 1998, the peak of the warming event in this region (Spencer et al. 2000). An immediate post-bleaching change in the benthic community composition of the fore-reef slope of Alphonse Atoll, southern Seychelles (Fig. 1) from 1998-2003 has been previously reported (Hagan and Spencer, 2006). Here, we report new findings from 2005 and 2007, focusing on the recovery and resilience of this reef system in terms of its scleractinian community, 9 years after a major bleaching event and following interaction with physical disturbance in the form of reef aspect-controlled wave damage.

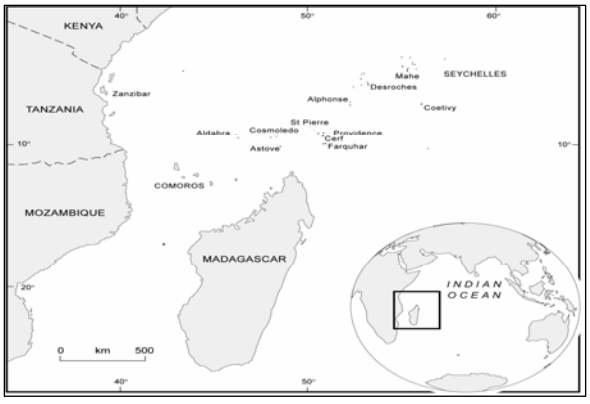

Figure 1: Location of the Seychelles, Western Indian Ocean (after Stoddart 1970). Note location of Alphonse Atoll.

Material and Methods

Alphonse Atoll (7°01'S; 52°44'E) lies at the southern extremity of the Amirantes Ridge, 415 km southeast of Mahé in the granitic Seychelles. It is a small (6 x 4 km; total area 11.28 km^2) symmetrical atoll, with peripheral reefs 640-1,900 m wide, covering an area of 4.02 km^2 (Stoddart 1984; Fig. 2). It has a 5.4 km^2 central lagoon which reaches a maximum depth of ~10m (Spencer et al. 2000).

The topography of the outer reefs at Alphonse can be separated into 3 distinct sections. Immediately seaward of the reef-flats, in less than 5 m water depth is a shallow rocky pavement characterized in places by distinct spur and groove formations. Spur and groove topography is particularly well developed on the north-west, leeward side of the atoll, where the U-shaped grooves are approximately 2 m deep. From -5 m to -15 m, a 50-150 m wide gently sloping rock surface extends down to a drop-off (Spencer et al. 2000), at -17 m to -20 m. The drop-off may either be a sheer vertical reef wall, as observed on both sides of the north-east tip of the atoll, or it may be a steep slope, as in the south-west.

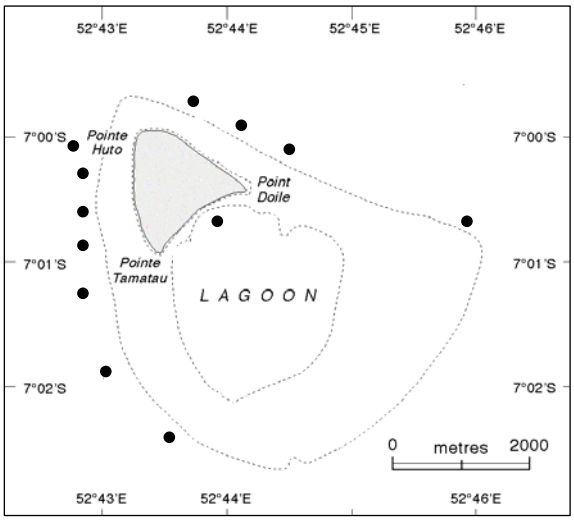

Figure 2: Location of survey sites at Alphonse Atoll; typically 1-3 depths surveyed at each site, ranging from -3.5 m to -18 m.

In 2001 and 2002, 30 permanent transect sites (29 fore-reef slope, 1 lagoon), encompassing a wide range of depths (-3.5 m to -18 m) and geographical aspects were selected. 15 m long transects were established parallel to the reef crest, marked with steel rods to aid re-location of the survey sites. Quantitative surveys were undertaken using standard video transect techniques. Video survey data was also obtained from 1998 (Hi8 format; Spencer et al. 2000) and 1999 (digital video; Teleki et al. 1999). A re-survey of all permanent transects was undertaken in 2003 and re-surveys of selected sites were carried out in 2005 and 2007.

Video data was analyzed using the AIMS 5-dot method (Osborne and Oxley 1997) to show changes in percentage cover for 7 benthic categories (sand, rubble, bare substrate, calcareous algae, Scleractinia, non-Scleractinia and macroalgae). Corals and algae were identified to genus level. Two datasets were generated; 'benthic categories data', from which percentage cover was calculated for each benthic category, and 'coral genera data'. Multivariate and univariate statistics were conducted, and dominance curves plotted, using PRIMER (Plymouth Routines In Multivariate Ecological Research) (Clarke and Warwick 2001).

At 7°S in the Western Indian Ocean, tropical cyclones are rare; frequencies for the area 0-10°S; 50-60°E are 2.1 per decade (Walsh 1984). However, in December 2006, Cyclone Bondo formed southwest of Diego Garcia and moved west across the Indian Ocean. It was a small but intense system (radius of hurricane force winds ~20 km) and category 2 strength (154-177 km h^{-1}) winds hit the Seychelles. The cyclone passed 330 km south of Alphonse Atoll, and although no terrestrial damage was observed, the associated wave field resulted in coral block detachment and transport on the northwestern side of the atoll, leaving a coral boulder debris field on the reef-flat (Plates 1 and 2). Coral blocks and dead *Porites* colonies, some measuring over 1 m in diameter, were observed in October 2007 on the reef-flat. Underwater surveys showed that these reef-flat deposits originated from depths of 7-12 m on the fore-reef slope and had been transported a horizontal distance of approximately 500 m.

Results

Benthic Categories Data – Temporal Community Change (1998-2007)

1998 data were only available for 5 transect lines, all of which were on the western fore-reef slope of the atoll. With such a small, localized dataset, these data cannot be assumed to be representative for the entire atoll. However, the 1998 surveys showed that live scleractinian cover ranged from 11.9-19.8% and bleached scleractinian cover values range from 8.9-19.4%. The combination of these values suggests that pre-bleaching, scleractinian cover represented between 20% and 40% of the benthos. In 1999, scleractinian cover represented between 8.8-13.7% of the benthic community, and in subsequent years, fore-reef slope scleractinian cover increased by over 5% in a 1-1.5 year period, from an average of 17.2% cover in 2001/02 to an average of 22.7% cover in 2003. However, between 2003 and 2007, there was no increase in average scleractinian cover (Table 1).

	Scleractinian Cover % ± 1 s.d.	Macroalgal Cover %
1998	14.8% ± 3.0	0.3
1999	10.3% ± 1.8	8.0
2001/02	17.5% ± 7.8	3.3
2003	22.6% ± 7.4	2.0
2005	22.2% ± 7.1	1.0
2007	21.2% ± 9.1	3.5

Table 1: Average scleractinian and macroalgal percentage cover 1998-2007 from video transect data.

Statistical tests between 1999 and 2001/02 on benthic percentage cover data showed no significant difference between these communities (ANOSIM; $P>0.05$) but there was a significant difference (ANOSIM; $P<0.01$) between 1999 and 2003.

Partitioning of these island-wide statistics shows marked differences in the time course of live coral cover changes between eastern and western survey sites. At eastern sites, a clear trend of increasing coral cover was shown 2001/02-2007 except for at the 5 m depth transect (Fig. 3). By 2007, scleractinian cover ranged between 24% and 38%. Conversely, the western sites showed a downward trend in scleractinian cover over this time period. Although scleractinian cover started off at a higher level in 2001/02 compared to eastern sites, there was a clear drop in cover in later years. By 2007, western sites displayed a maximum of 16% live scleractinian cover (Fig. 4).

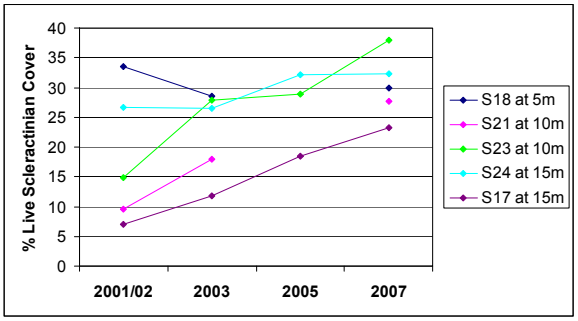

Figure 3: Scleractinian percentage cover change over time at five eastern sites. (Each line represents single transect at one depth).

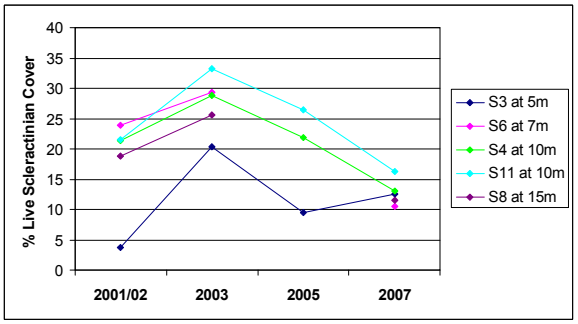

Figure 4: Scleractinian percentage cover change over time at five western sites. (Each line represents single transect at one depth).

Coral Genera Data – Temporal Community Change (1998-2007)

k-dominance curves (Fig. 5) for each of the survey years show the change in the scleractinian community composition 1998-2007. Curves for 2001/02 and 2003 cross those of 1998 and 1999, so it is inappropriate to comment on the comparison between all four curves (Lambshead et al. 1983). However, the curve for 1999 lies below that of 1998, indicating increased biodiversity in the 1999 coral genera dataset compared to the 1998 dataset. The curve of 2001/02 lies below that of 2003, indicating that the coral community of 2001/02 was more diverse than that of 2003. There appears to have been a small increase in diversity between 2003 and 2005 but this decreased again by 2007.

Coral genera diversity has decreased over time, with the lowest diversity (i.e. the highest *k*-dominance curve) being seen in 2007 (Fig. 5). The point at which the curves cross the y-axis becomes increasingly higher in later years, and by 2007, 60% of the scleractinian community was accounted for by just one genus.

Pielou's Evenness (J') (how evenly the individuals are distributed among different genera) was seen to increase between 2003 and 2005, but decrease between 2005 and 2007, supporting the findings of the *k*-dominance curves. The difference between mean Evenness values over the time series is statistically significant (ANOVA; $F = 3.53$, $P<0.01$).

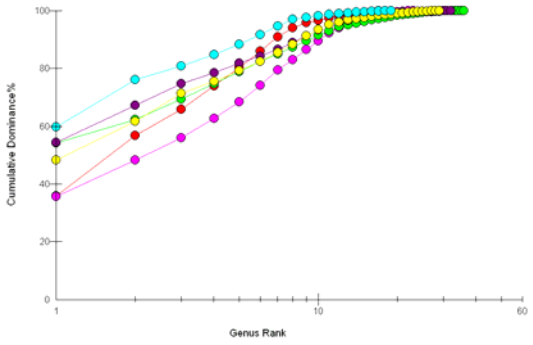

Figure 5: *k*-dominance curves for 1998 (red), 1999 (pink), 2001/02 (green), 2003 (purple), 2005 (yellow) and 2007 (turquoise) using coral genera data from video surveys.

Discussion

The 1997-98 bleaching event had a considerable impact on the community composition of the fore-reef slope of Alphonse Atoll. In 1998, at the height of the bleaching event, live scleractinian cover was reduced to an average of 14.8%, and this value had further decreased one year after the bleaching event (Table 1). By 2003, scleractinian cover had more than doubled from 1999 levels. Taking 1999 as the first year that gives a true indication of actual mortality suffered at Alphonse (1998 surveys were taken at time of on-going bleaching), this implies that a period of at least 4 years (1999-2003) was required after this major disturbance before any statistically significant recovery in scleractinian community cover could be observed.

Coral genera diversity increased between 1998 and 1999, as illustrated by the 1999 curve being lower than that of 1998 on the *k*-dominance plot (Fig. 5). However, between these two years, a decrease in live scleractinian percentage cover was calculated. The increase in biodiversity but decrease in total coral cover that was observed at Alphonse between 1998 and 1999 may imply that the bleaching event quickly removed certain genera from the 1998 dataset. However, some of these genera may have made a rapid return to the reef in 1999, increasing biodiversity levels, although their small size would not have increased the percentage cover values for that year. There was a further decrease in scleractinian diversity between 2001/02 and 2003, and again between 2005 and 2007. The *k*-dominance curves (Fig. 5) and Pielou's Evenness values indicate that in later years, there has been a reduction in diversity in the scleractinian community present and increased dominance by a few (or even just one) coral genera.

The dominant (in terms of percentage cover) scleractinian genus on the fore-reef slope of Alphonse in 2007 was *Porites*. Due to the size of many of the *Porites* colonies observed (some measured over 2 m across), it is clear that these massive, slow-growing colonies must have survived the 1998 thermal stress. In addition, lagoon corals and many shallow water corals also survived, presumably by being acclimatized to warmer water conditions (Spencer et al., 2000). The survival of these pockets of corals is likely to have improved reef resilience on the fore-reef slope at Alphonse, with these colonies acting as larval sources to re-seed degraded areas.

The second most dominant genus in 2007 was *Pocillopora*, which was widespread on all reefs at Alphonse. *Pocillopora damicornis* has been described as an opportunistic species, due to its rapid reproductive cycle and fast growth rate, enabling it to quickly occupy any newly available space (Endean and Cameron, 1990).

The granitic Seychelles islands in the north suffered over 90% coral mortality during the 1997-98 ocean warming (Wilkinson, 2000) but the southern islands were less severely affected, with an average mortality of around 60% (Spencer et al. 2000). It is suggested that this difference was due to the moderating influence of the South Equatorial Current at the southerly locations, in contrast to the heating of shallow waters, and long water residence times, on the Seychelles Plateau. As more of the corals at Alphonse survived the bleaching event compared to reefs of the granitic Seychelles islands, it can be suggested that reef resilience at Alphonse has been aided by the interaction of geographical location with regional oceanographic processes.

Another of the main factors driving reef resilience at Alphonse has been the minimal anthropogenic impact, which may have allowed more rapid natural reef regeneration than in areas with high human pressure (as has been demonstrated elsewhere; Sandin et al. 2008). Alphonse has a very small resident population (~60 people) and tourism is small-scale, with only 30 double chalets. Boat traffic at Alphonse is minimal (a maximum of 4 boats over 10

m in length were in operation at time of reef surveys) and anchoring on the reef is prohibited.

Variations in coral cover histories on reefs of differing aspect require further investigation. Cyclone Bondo caused extensive damage in a localised area on the northwest fore-reef slope, but a downward trend in live scleractinian cover was already evident in 2005 (Fig. 4). It is not known what caused this decline. One possibility is wave refraction around the atoll during the December 2004 Asian tsunami and consequent disturbance of coral cover, although general tsunami impacts in the southern Seychelles were low in littoral environments (Hagan et al., 2008).

Despite a rapid increase in macroalgal cover one year after the peak of the bleaching event, the Alphonse reefs have not succumbed to the algal 'phase shift' from a 'hard' reef community to a 'soft' reef community (Done 1999) that has been seen after reef disturbance elsewhere. An altered fore-reef slope coral community appears to exist at Alphonse 9 years after the ocean warming related mortality. Large skeletons (1-3 m diameter) of *Porites* spp., *Lobophyllia* spp., and *Symphyllia* spp. have been colonized by *Pocillopora* spp. and to a lesser extent *Acropora* spp., suggesting that the Alphonse fore-reef slope may be in an interim phase of development, through which the coral community must pass before regaining high levels of coral coverage and diversity.

Alphonse provides one of the most detailed long-term (>9 yrs) records of post-bleaching reef dynamics in the Western Indian Ocean and demonstrates not only the general interaction between physiological and physical disturbances (where human impacts can be disregarded) but also the complexities of response by atoll environment (fore-reef slope, reef crest, lagoon) and reef aspect. Continued monitoring may shed more light on the nature of these controls on reef resilience and recovery.

Responses of coral hosts and their algal symbionts to thermal heterogeneity

H.M. Putnam and P.J. Edmunds,
California State University, 18111 Nordhoff Street, Northridge, CA 91330-8303

Abstract The effects of high temperature on tropical corals have been studied extensively, but little is known of their response to high frequency thermal fluctuations that are common in many reef habitats. To better understand how oscillatory temperatures affect corals, *Pocillopora meandrina* and *Porites rus* from the lagoon of Moorea were used to test the effects of fluctuating temperatures on coral physiology. Corals were incubated at a stable temperature (28 ºC), or diurnally fluctuating temperatures (26 – 32 ºC) that simulate the conditions in the lagoon. Their response was assessed through dark-adapted maximum quantum yield (F_V/F_M), *Symbiodinium* density, and holobiont respiration. Following incubations, *Symbiodinium* density and F_V/F_M were depressed 25 - 42%, and 20 - 23%, respectively, for both species under fluctuating compared to the stable temperature treatment. Additionally, respiration was 55-63% lower in the fluctuating compared to the stable conditions, although this effect was only found in one of two replicate experiments. These results demonstrate that corals can be strongly affected by diurnal temperature fluctuations in lagoon habitats.

Key Words: temperature, fluctuation, physiology, *Pocillopora meandrina*, *Porites rus*

Introduction

To date, most research on the response of scleractinian corals to thermal stress has considered steady exposures to high temperatures, even though there is evidence that many reefs experience oscillatory thermal regimes with diurnal ranges as great as 9 ºC (Lee et al. 1999, Leichter et al. 2006, Craig et al. 2001). Indirect evidence suggests that such variability can have important effects, for instance, as shown by the association between the variance in temperature and the severity of coral bleaching (McClanahan et al. 2007). The lack of attention to the effects of fluctuating temperatures on corals has important implications, as most efforts to predict the ecological consequences of coral bleaching, as well as the limits of thermal tolerance for corals (e.g., Hoegh-Guldberg 1999), are based on a tacit assumption that temperature is constant on a scale of days to weeks.

In order to understand the full range of responses of corals to thermal stress, studies are required that evaluate the impacts of fluctuating temperature, in addition to the more frequently studied effects of constant temperature regimes. The purpose of this study was to examine the effects of thermal fluctuations that are ecologically relevant for the lagoon of Moorea (i.e., a 6 ºC change within 24 h) on coral physiology. Specifically, we tested the hypothesis that rapid fluctuations in temperature have strong effects on the physiology of the cnidarian host and the *Symbiodinium* symbionts of two species of coral.

Material and Methods

To characterize the thermal regime in the lagoon of Moorea, seawater temperature at ≈3 m depth was measured using loggers (0.02 ºC resolution and 0.0017 Hz sampling frequency) between 2005 and 2006 (Fig. 1a). These temperature records revealed diurnal fluctuation with daytime heating and nighttime cooling (Fig. 1b). To test the hypothesis that such fluctuations affect coral physiology, two consecutive experiments were completed using common lagoon corals -- *Pocillopora meandrina* and *Porites rus* -- in April (trial 1) and May (trial 2) of 2006. Manipulations took place near the end of the Austral summer, which corresponds to a period of higher seawater temperature (Fig. 1a). Corals were collected from 2-3 m depth, and prepared as nubbins. The nubbins were allowed to recover from the collection process for 18-24 h in flowing seawater, and then were placed in the treatment tanks 3 d before the experiments began to allow the corals to acclimate to the ambient conditions at 28 ºC.

Experimental manipulations were used to create a comparison of diurnal thermal fluctuation, and a steady temperature (≈28.6 ºC, which served as the control and simulated mean ambient lagoon conditions during April and May 2006). The fluctuating treatment repeatedly exposed corals to

≈26ºC and ≈32ºC by transferring the nubbins daily from a tank at ≈26 ºC to a tank at ≈32 ºC at 07:00, and back to the ≈26 ºC tank at 19:00, which mimicked extreme diurnal temperature fluctuations in the lagoon. A procedural control was created by moving additional nubbins in and out of a tank held at the ambient temperature (≈28.6 ºC). Nubbins remained submerged in a beaker of seawater during all transfers, and care was taken not to touch the tissue.

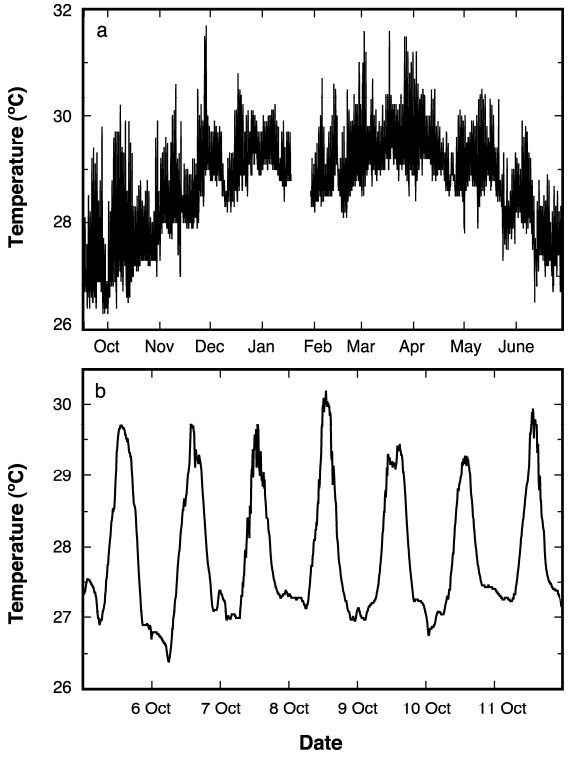

Figure 1. Representative record of seawater temperature in the lagoon (≈3 m depth, 10 min sampling interval) of Moorea from September 2005 – June 2006. (a) The 10-month record shows seasonal variation as well as high frequency changes occurring on a scale of hours-days; the ticks on the abscissa correspond to the first day of each month. (b) Seawater temperature from a 7 day period of strong diurnal fluctuation (~3.5 ºC) during October 2005. The temperature maxima correspond to midday solar warming, and the minima occur between 19:30 – 07:30; the ticks on the abscissa correspond to 0:00 hours.

The manipulations took place in an outdoor microcosm that housed 135 L tanks, each with a separate chiller, heater, and pump, and filled with seawater that was refreshed daily (~20% d^{-1}). To simulate light levels at the collection depth, the tanks were shaded to ≈1,000 µmol photons m^{-2} s^{-1} at noon. Light levels were recorded daily inside each tank, and the temperature was measured every 10 min using loggers (HOBO® and StowAway®, accuracy ±0.2 ºC). Each experiment began at 12:00 on day 1 and ended at 19:00 on day 8, and measurements began immediately following.

Response Variables- Samples sizes differed among the three variables, and also by treatment (Fig. 2). To examine the effect of the treatments, the response of the *Symbiodinium* was measured as maximum dark-adapted quantum yield of PSII (F_V/F_M) and their population density. The performance of the holobiont was measured as dark respiration of the intact coral, which reflects the combined effects of the cnidarian host and the algal symbiont.

F_V/F_M was recorded using a Diving-PAM (Walz, GmbH), and all measurements were made on the final night of the experiment, following 2.5 h of darkness. To determine F_V/F_M, each coral was removed from its treatment tank in a darkened beaker filled with seawater (500 mL), and a single measurement was made using the 5.5 mm fiber-optic probe of the Diving-PAM. A single measurement was used per nubbin to reduce the effect of the measuring light on subsequent F_V/F_M measurements (i.e. subsequent measurements result in significantly increased F_M, $t=2.67$, $df=166$, $p<0.05$). To minimize variation in F_V/F_M due to location of the probe, measurements were taken ~2 cm below the branch tips.

To quantify the *Symbiodinium*, the skeleton was removed from the fixed tissue (5% formalin) by decalcification (10% HCl). The tissue layer resulting from decalcification was homogenized using an ultrasonic dismembrator (Fisher 15-338-550) fitted with a 3.2 mm diameter probe (Fisher 15-33867). The homogenate was suspended in freshwater, and six replicate counts of *Symbiodinium* were completed using a hemocytometer. An aliquot of the slurry was dried at 60 ºC to determine biomass, and the *Symbiodinium* population density was expressed in units of cells mg^{-1}.

Dark respiration was measured as O_2 consumption within a PVC chamber (0.89 L), which was attached to a submersible pump in a closed circuit. As estimated by photographing hydrated brine shrimp eggs, flow speed inside the chamber was 23.1 ± 1.0 cm s^{-1} (mean ± SE, n=15), which approximated the mean flow speeds in the lagoon during the experimental period (R. Carpenter, pers. comm.). A single coral nubbin was placed in the seawater-filled darkened chamber, and the sealed system immersed in a 135 L tank to regulate temperature. The reduction in O_2 concentration due to respiration was measured at ambient temperature (28.2 ± 0.1 ºC [n = 24] in trial 1 and 27.8 ± 0.1 ºC [n = 26] in trial 2) over 25 min using a fiber optic probe (FOXY-R, Ocean Optics). All measurements were completed between 80 and 100% O_2 saturation to avoid O_2-dependent effects on respiration, and the rates of O_2 consumption were corrected for control values obtained by measuring O_2 consumption in a seawater-filled chamber, with no coral. Respiration rates were normalized to surface

area of the coral (obtained by aluminum foil) and reported in units of μmol O_2 cm^{-2} min^{-1}.

Statistical Analysis- The experiment was designed to be analyzed with a mixed-model nested ANOVA in which repeated experiments were used to strengthen the interpretation of treatment effects, but this design was precluded by a trial effect driven by weather-related differences in light and temperature. Due to significant differences in light regime and temperature between trials (data not shown), data were analyzed separately by trial using two-way Model I ANOVAs in which treatment and species were fixed effects, and F_V/F_M, *Symbiodinium* density, and dark respiration were dependent variables. The random placement of nubbins in each tank every day removed potential biases attributed to position effects. Data were assessed for normality and homoscedasticity using a graphical analysis of residuals, and were transformed where necessary (log transformations for respiration).

Results

Light levels within the tanks were significantly higher in trial 2 compared to trial 1 (data not shown), and corals were exposed to a slightly greater diurnal range of temperatures (i.e., a lower minimum and higher maximum) in trial 1 (5.9 ºC) than in trial 2 (5.1 ºC).

Maximum Quantum Yield (F_V/F_M)- For *Pocillopora meandrina, F_V/F_M* over both trials ranged from 0.67-0.76 in the control treatments, and 0.50-0.69 in fluctuating temperature treatments. For *Porites rus*, F_V/F_M in both trials ranged from 0.62-0.71 and 0.51-0.67 in control and fluctuating temperature treatments, respectively. F_V/F_M was significantly affected by treatment ($F_{1,55}$ =162.79, $p < 0.001$) and species ($F_{1,55}$ = 1.178, $p < 0.01$) in trial 1, but there was no interactions of the main effects ($p > 0.05$). A similar outcome of lesser magnitude was observed in trial 2, with F_V/F_M affected significantly by treatment ($F_{1,54}$ = 20.20, $p < 0.001$) and species ($F_{1,54}$ = 39.10, $p < 0.001$), but not the interaction between the two ($p > 0.05$) (Fig. 2a and 2b). These decreases of F_V/F_M corresponded in trial 1 to a reduction in the fluctuating treatment of 23% for *P. meandrina*, and 20% *P. rus*, when compared to the control treatment. The same pattern was present in trial 2, but the reductions of F_V/F_M in the fluctuating treatment were smaller (4% and 3% for *P. meandrina* and *P. rus*, respectively).

Symbiodinium Density- At the conclusion of the two experiments, most of the corals in both of the treatments were slightly pale in color (relative to freshly collected corals). The *Symbiodinium* density changed significantly for both species after exposure to the fluctuating temperatures in trial 1 ($F_{1,26}$ = 5.64, $p < 0.03$), but not in trial 2 ($p > 0.05$) (Fig. 2c and 2d). Mean *Symbiodinium* densities were reduced ~42% in *Porites rus* and ~25% in *Pocillopora meandrina* in the fluctuating treatments of trial 1. Neither the species, nor the interaction of species and treatment, were significant for either trial ($p > 0.05$).

Respiration- Mean dark respiration ranged from 0.017 – 0.046 μmol O_2 cm^{-2} min^{-1} for *Pocillopora meandrina,* and from 0.012 – 0.032 μmol O_2 cm^{-2} min^{-1} for *Porites rus* (Fig. 2e and 2f). Respiration rate was reduced significantly in the fluctuating treatment in trial 1 ($F_{1,9}$ = 13.751, $p < 0.01$) for both *P. meandrina* and *P. rus*, and differed significantly between species ($F_{1,9}$ = 4.955, $p = 0.05$). There was no significant treatment x species interaction for trial 1, or for any factor or interaction in trial 2. The reduction in respiration due to the fluctuating treatment in trial 1 corresponded to a 63% and 55% decrease for *P. meandrina* and *P. rus*, respectively, when compared to the control treatment. In trial 1, the respiration of *P. rus* was ~32% lower than *P. meandrina* at ambient temperature, and ~43% lower in the fluctuating treatment, but in trial 2, the respiration rates were statistically identical in the two corals.

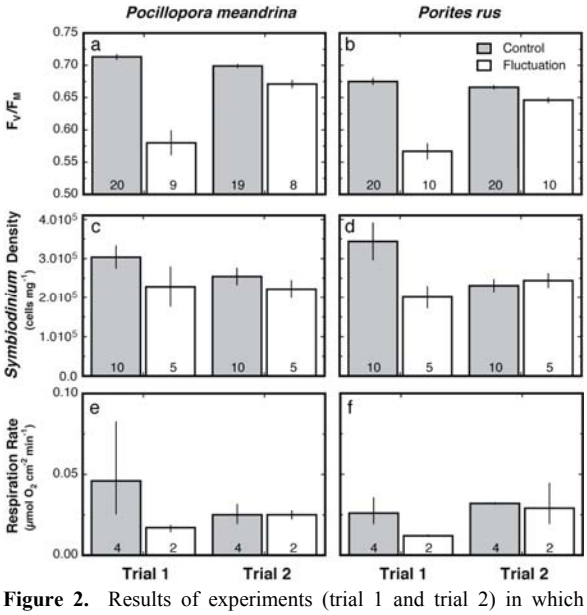

Figure 2. Results of experiments (trial 1 and trial 2) in which corals were exposed to a steady temperature of 28 ºC (control) and a fluctuating treatment consisting of 12 h exposures to ~26 and 32 ºC; (a,b) maximum dark-adapted quantum yield of PSII (F_V/F_M), (c,d) *Symbiodinium* density, and (e,f) dark respiration. Results are displayed as mean ± SE for F_V/F_M and *Symbiodinium* density, and as mean ± SD for back-transformed values for respiration; sample sizes shown within each bar.

Discussion

On many tropical reefs, corals can experience rapid changes in water temperature of a sizable magnitude within minutes to seconds (Leichter et al. 2006, Craig et al. 2001). This study presents some of the first evidence that such temperature oscillations have significant effects on corals, with the direction of response for the measured variables suggesting that the outcome is detrimental to the coral. *Symbiodinium* population density and their function (F_V/F_M), as well as the respiration of the holobiont, all were lower as a result of exposure to fluctuating temperatures, compared with corals exposed to steady temperatures. If corals respond differently not only to a consistent exposure to high temperatures, but also to the thermal oscillations, quantification of their response to fluctuations in temperature will be critical to accurately predict the response of coral communities to the changes in seawater temperature that are forecast for the next century (IPCC 2007).

In the present study, exposure of corals to fluctuating temperatures resulted in a lower efficiency of photophysiology of the algal symbionts, relative to those maintained under control conditions. The magnitude of the decrease of F_V/F_M in *Pocillopora meandrina* and *Porites rus* is likely indicative of chronic irreversible photodamage to PSII of the algal symbionts (Brown et al. 2000, Fitt et al. 2001), and the evidence for this conclusion is twofold. First, there was no sign of the depressed F_V/F_M values returning to the initial levels throughout the experiment (data not shown), as would be expected with reversible photodamage (Fitt et al. 2001). Second, the loss of photosynthetic capacity (F_V/F_M) is juxtaposed with the loss of *Symbiodinium* from the host tissue (Fitt et al. 2001), which is usually interpreted as the terminal phase of coral bleaching, and occurs in association with damage to the symbiont through oxidative stress (Lesser 1997, Fitt et al. 2001). Unfortunately, one limitation of the current study was an inability to compare the effects of the fluctuating temperature treatment and a steady exposure to each of the extreme temperatures, which is necessary to determine whether oscillatory temperatures elicit a response that is the sum of the effects of the component temperatures, or a response of a different nature.

Fluctuating temperatures reduced the F_V/F_M of *Pocillopora damicornis* and *Porites rus* by 19% and 16%, respectively. This reduction is comparable to the decrease in F_V/F_M of *Acropora palifera* and *Pocillopora damicornis* (~8 - 25%) during a natural thermal bleaching event at Heron Island in March 1998, which followed a 2-3 d period over which the seawater temperature was unusually variable (~26-34 ºC within 24h) (Jones et al. 2000). The reductions in *Symbiodinium* density as a result of fluctuating temperatures in the present study (~25 - 42%) fall within the range of losses reported during natural bleaching events (Brown et al. 1995, Jones et al. 2000, Edmunds et al. 2003). Along with clear treatment effects, there was also a significant difference between F_V/F_M for the two species. Determining why these species differ was beyond the scope of this study -- although it is intriguing to speculate that they harbor different taxa of *Symbiodinium* (Rowan 2004) -- but importantly, the absence of a treatment x species interaction for F_V/F_M indicates that *P. rus* and *Pocillopora meandrina* responded to the treatments in similar ways.

In the present study, the fluctuating temperature treatment resulted in decreased respiration compared to the control conditions for both species, at least in one of the two trials. While within the range of values reported for congeners (Edmunds and Davies 1986, Rex et al. 1995), respiration rates characteristically increase with rising temperature. A likely explanation for the lower respiration rate in the fluctuating treatment in the first trial is that it reflected the consequences of a decrease in quantity of photosynthetically fixed carbon translocated to the animal, which is thought to stimulate the metabolism of the host (Szmant and Gassman 1990), either due to a decrease in *Symbiodinium* function (as assessed by F_V/F_M), or a reduction in their population density (Szmant and Gassman 1990, Castillo and Helmuth 2005). In this situation, lower rates of respiration are likely to reflect a negative effect of temperature.

A second explanation for the decline in respiration rates in the first trial, is that it reflects a beneficial response to fluctuating temperatures (Barshis et al. 2008), and therefore could be described as acclimatization. In this situation, lower rates of respiration are arguably a positive response to temperature. However, it is challenging to interpret the implications of changes in metabolic rates, particularly in a mutualistic symbiosis where the holobiont respiration reflects the sum of the parts. Clearly, a more detailed analysis of the causes of the change in respiration rates as a result of fluctuating temperatures in the present study (as well as why it was absent in the second trial) are necessary.

In the present study, the differences between trials in the response of both corals to fluctuating temperature were unexpected given the considerable effort expended to replicate the treatment conditions. A reason for the differences in response to the fluctuating treatment between trials may be temporal variation in environmental history of the experimental corals (i.e., differences in light and temperature prior to collection). While corals were collected from the same location and depth for both trials, the additional

time (11 d) spent at local environmental conditions by the corals used in trial 2 may have had an effect on their ability to respond to extreme fluctuations. As noted previously the second trial was completed following the peak temperatures and therefore it is possible the differences in response in trial 2 may be a result of lower stress on the corals, due to the associated decrease in temperature in the field.

A greater magnitude (~16% greater) of diurnal temperature variation occurred in trial 1 compared to trial 2, and most interestingly was associated with a stronger response to the fluctuations in host and symbiont, at significantly lower light levels. This finding suggests that thermal fluctuation may act in a threshold fashion with regards to the magnitude of the fluctuations. Above this threshold, the effects of large temperature fluctuation at reduced light levels are more severe than the effects below this threshold, where small temperature fluctuation may confer protection against the effects of higher light levels, which are generally thought to accentuate thermal bleaching (Brown 1997, Hoegh-Guldberg 1999).

Abstract: Long term viability of coral communities is dictated by their ability to withstand environmental change. Three "mechanisms" exist by which reefs may survive stressful conditions: (1) physiological tolerance, (2) via environmental refuge, and (3) repopulation and growth (recovery) once ambient conditions return. During the 1998 El Niño event, sea surface temperatures (SSTs) around the Seychelles persisted above 32°C and more than 75% of all reefs bleached. Since then, SSTs have not exceeded 30-31°C allowing reefs to recover. Analyses of the size frequency distribution of species-specific colonies in the Seychelles indicated that certain species survived the 1998 event (termed type II corals) whilst other species (termed type I corals) did not but have recruited into the systems post 1998. Experiments confirmed type I and II coral species exhibited alternative physiological characteristics that likely determined the post 1998 community. Turbid lagoons containing large colonies of type I species were identified within an oceanic atoll (Desroches) suggesting that these species survived 1998 by recruiting into what have been previously considered sub-optimal habitats and were likely buffered against environmental stress. Consequently, several mechanisms are in active operation that appears to afford Seychelles' reefs some long term resistance to extreme periods of environmental change.

Key words: Seychelles, bleaching, photosynthesis, coral community structure, refuge

Introduction: Aquatic environments are subjected to environmental change, the periodicity of which occurs across a continuum from the short term, (physiological acclimation) to the longer evolutionary term (genetic adaptation). Coral reefs are no exception; in fact the near surface, shallow water, habitat of most reefs accentuates the scale of variability with which corals are exposed to life sustaining resources, primarily light, temperature and nutrition. As such, corals are adapted to living in a highly variable world; however, the Earth is currently experiencing a rate of unprecedented environmental (climate) change that vastly exceeds the rate of evolution and thus places stress on corals' pre-adaptations to environmental variability.

Typically, corals have three "mechanisms" to survive stressful conditions: (1) physiological *tolerance* until conditions return to a nominal 'steady state', which may require resources to be directed from growth and reproduction to cellular repair and maintenance; (2) *refuge* in environments that are not experiencing the same degree of stress; and (3) population *recovery* by new recruitment. Importantly, coral community structure is directly related to the extent of trophic complexity (Graham et al. 2006). Therefore, the relative activity of these mechanisms will determine future coral community composition and productivity and in turn the entire reef ecosystem. The fundamental ecological unit is the species whilst within coral systems reef building corals are the key ecosystems architects; as such, it is crucial that we understand how coral species respond to stress and how linked ecological systems will be affected. As such, it is imperative that we understand the type and extent of "mechanism" selected for in response to environmental variability by key reef building corals.

Coral reefs of the Seychelles are well recognized to have been heavily impacted by the 1998 El Niño event: sea surface temperatures (SSTs) around the Seychelles persisted above 32°C for several weeks and more than 75% (upto 95% in some cases) of all reefs bleached (Goreau et al. 2000, Spencer et al. 2000). Whilst elevated temperature is believed to be the primary factor that induces bleaching, light is also recognized as a factor that can modulate the rate and extent with which the elevated temperature impacts coral functioning (e.g. Smith et al. 2005; Brown & Dunne 2008). Bleaching describes the depigmentation of corals and is thought to occur primarily from loss of, or photosynthetic down-regulation by, the zooxanthellae (Smith et al. 2005). The coral host cannot survive for long periods without a sustained

energetic contribution by the symbiotic algae and the host coral eventually dies. Consequently, bleaching events provide an important indicator of reef response to relatively large, sometimes irregular changes in climate. ENSO events can thus be used as a 'natural' experiment to examine species/community responses to climate driven environmental stress: since 1998 records indicate that SSTs of the Seychelles have not exceeded 30-31°C potentially allowing reefs to recover from repeat exposure (e.g. see NOAA data for Mahé: www.coralreefwatch.noaa.gov/satellite). The limited data for the Seychelles suggests that in the first 5 years following the El Niño event, % live coral cover for Seychelles' islands increased from ca. 3 to 15 % and from ca. 3 to 6% for granitic and calcareous reefs, respectively (Payet, Bijou & Adam in Linden et al. 2005), and so is in an active state of recovery.

Both the immense negative impact of the 1998 El Niño event and subsequent apparent recovery of Seychelles' reefs afford an important natural system to examine how coral reefs respond to environmental change; in particular, how communities recover once growth conditions re-establish towards 'steady state' (Graham et al. 2006). We tested the hypothesis that "species existing as large colonies were least susceptible to stressful environmental conditions" by addressing 3 primary objectives: (1) Examine the size frequency distribution of colonies within a region that was very heavily impacted by the El Niño event and determine which species survived using size as a proxy for age; (2) Identify key physiological characteristics of species deemed to have survived 1998 versus those absent from the system pre 1998 (but present during 2006-7); and (3) Determine if susceptible species survived the 1998 ENSO event through refuge in light-limited environments.

Materials and methods: Coral community structure was examined at two islands in the Seychelles in August 2006 and 2007: (1) the granitic island of Silhouette (off the North East coast of Mahé) and (2) the coral atoll of Desroches (ca. 240 km off the south-west coast of Mahé). 30m continual line intercept transects were used to estimate species specific % cover and 20 m^2 quadrats (at the start of each transect) used to determine the size frequency distribution of hard corals (n = 1800 at all sites and transects). Fragments of key species (*Acropora formosa*, *A. horrida*, *Diploastrea heliopora*, *Favia speciosa*, *Fungia sp*., *Pocillopora eydouxi*, *P. verrucosa*, *Porites lutea*, and *P. nigrescens*) were taken from 5-8m for physiological measurements in the laboratory; only large (older) colonies were examined.

Respirometry— Each fragment was placed within a custom build respirometer; changes in O_2 were logged continuously using an *Optode* (Aanderaa

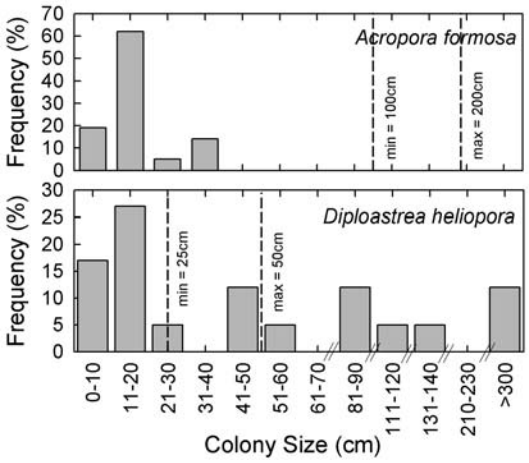

Figure 1. Size (cm)-frequency (%, of all colonies measured) distributions of key coral species from Silhouette high light environment). Examples are shown here for *A. formosa* (type I species n = 45) and *D. heliopora* (type II species, n = 60). Colonies of all other species (n = 32) identified were measured and could be classified as either type I or II corals. Dashed lined indicate size attained by 1998 based on maximum and minimum reported growth rates (see main text).

Inc., Denmark). Temperature was also logged with the *Optode* but did not increase by > 0.25 °C above ambient for any incubation: Initially, O_2 consumption was measured in the dark. A gradient of increasing light between ca. 10 and 1000 µmol photons m^{-2} s^{-1} was subsequently delivered to examine the light response of photosynthesis (P-E). Respiration measurements were again repeated at the end of the P-E run. Each light step (and respiration) was delivered for 15-20 mins. The light intensity was measured within the respirometer upon the surface of the coral using a PAR sensor after each experiment. Daily *in situ* photosynthesis and respiration rates were approximated by applying the P-E characteristics and respiration rates to measurements of the diel light climate from a HOBO (Tempcon Inc., USA) logger at the sampling site. Rates were normalized to coral surface area, as determined using the foil technique.

Thermal tolerance experiments— All fragments were placed in a community tank gradually increased over 3 hours from ambient (ca. 26ºC) to elevated (32ºC) temperature. Photosynthetic physiology was monitored prior to experimentation and then every 12 hours at the elevated temperature using diving PAM fluorometry (following Hennige et al. 2008). Changes of the maximum fluorescence yield (F_m, instrument units) and PSII photochemical efficiency (F_v/F_m, dimensionless) were used as course proxies for symbiont biomass and photosynthetic competency in response to elevated temperature. Both temperature and O_2 saturation were monitored continuously using the *Optode*. Water was changed every ca. 12 hours to minimise the reduction in O_2 saturation (never <

90%), in particular, as corals began to discolor or slough tissue from the host and into the tank.

Results: We will consider each objective in turn from data collected at Silhouette (objective 1 and 2) and Desroches (Objective 3).

Objective 1— Size frequency data were treated so as to estimate whether corals had survived the 1998 bleaching event: coral size expected for the 1998 growth year was estimated from the product of growth rate (cm y^{-1}) and number of years since 1998 (9 for Silhouette). In this way, fast growing species would of course be expected to be much larger than slower growing species assuming that 'cropping', by physical or biological processes are negligible. Growth rates used were the maximum and minimum recorded growth rates for clear waters (see Crabbe & Smith 2005). As such, the predicted sizes for 1998 were highly conservative given known inherent variability of coral growth across species, size class and environment. These predicted sizes (max-min) for 1998 are plotted as the thick vertical broken line in Fig. 2. Size frequency distributions that fall to the left of this line are indicate of colonies that have recruited post 1998; in contrast, those to the right of this line are indicative of colonies that have recruited pre-1998 and so survived the 1998 El Niño bleaching event. Of the key species examined, the acroporid and pocilloporid colonies all appeared to be post 1998 recruits (Fig. 1) whilst some species (*D. heliopora*, *F. speciosa*, *P. lutea*) exhibited colonies that were larger than would be predicted for 1998 (Fig. 1), with some *D. heliopora* and *P. lutea* colonies greater than 5m (data not shown). Corals within these two groups will subsequently be referred to as type I (recruited post 1998) and type II (survived 1998) corals, respectively.

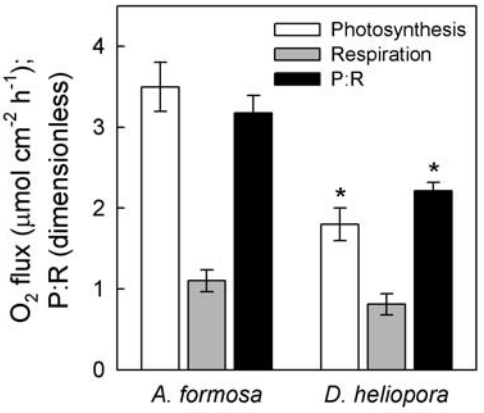

Figure 2. Rates of O_2 production (photosynthesis, P) and consumption (respiration, R), mmol O_2 cm^{-2} h^{-1}), and rates of P expressed relative to R (P:R, dimensionless). Examples are shown here for *A. formosa* and *D. heliopora* (mean ± SE, n = 3). All other species examined followed patterns the same as for *A. Formosa* (*A. horrida, P. eydouxi, P. verrucosa*, referred to as 'type I' corals) or *D. heliopora* (*F. speciosa*, *P. lutea*, referred to as 'type II' corals) (data not shown). Daily rates have been adjusted to hourly rates here. Asterisks represent significant differences between the two species for a t-test performed for each variable (i.e. P, R or P:R).

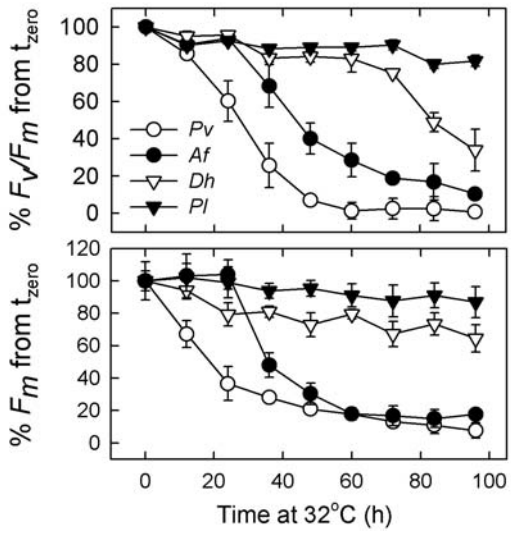

Figure 3. Mean percentage (%) ± standard error (n=3) change in photosynthetic parameters F_v/F_m (the maximum PSII photochemical efficiency) and F_m (the maximum fluorescence yield), measured by PAM fluorometry, with time of exposure of corals to elevated temperature of 32ºC (hours). Percentage change is expressed relative to values at time zero (t_{zero}). Examples are shown here for type I corals *P. verrucosa* and *A. formosa* and type II corals *D. heliopora* and *P. lutea*. All other species followed these type specific patterns (data not shown).

Objective 2— Both respirometry and PAM fluorometry demonstrated that type I and II coral species exhibited very different physiological characteristics. Rates of photosynthesis were higher by a factor of ca. 1.5-2.0 for type I than for type II corals (Fig. 2). Rates of respiration were similar across all species tested. Together these data yield photosynthesis to respiration ratios (P:R) that were highest for the type I corals (Fig. 2). PAM fluorometry was used to test for the response of type I and II corals to thermally induced stress (Fig. 3). The % change in maximum PSII photochemical efficiency (F_v/F_m) relative to time zero was greatest and occurred most rapidly for type I corals. Typically, F_v/F_m decreased by ca. 80-100% of the initial value after 40 to 60 hours at 32ºC (Fig. 3). In contrast, type II corals only exhibited a decrease of F_v/F_m by 40-20% of the initial value after 100 hours at 32ºC. Importantly, these responses by type I and II corals represent very different bleaching processes. For type I corals the decrease in F_v/F_m was the result of tissue sloughing off of the skeleton. The decrease in F_v/F_m

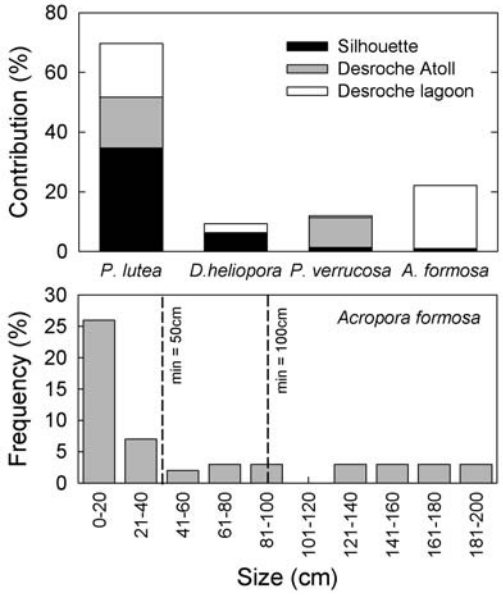

Figure 4. Relative contribution (%) of the four key coral species to the hard live coral community at each site: Silhouette (n=15), Desroches atoll (n=15) and lagoon (n=25). Lower panel is size frequency of *A. Formosa* colonies measured in the turbid lagoon (n = 53).

actually represents an increase in contamination to the minimum fluorescence yield from the skeleton (not shown) and so is not a physiological response from the zooxanthellae *per se*. This is representative of an ***acute*** bleaching response that appears to primarily target the host. Thus, the decline in symbiont biomass (i.e. the maximum fluorescence yield, F_m) is directly from a loss of coral host tissue containing the symbiont and occurs as abruptly as the change in F_v/F_m. In contrast, type II corals exhibited a gradual decline in F_m where the symbionts downregulated photosynthetic activity (Fig. 3). Here, host tissue remains in tact on the host skeleton and represents a ***chronic*** symbiont-targeted bleaching response.

Objective 3— Live coral cover estimated from all transect surveys at Silhouette and Desroches (outer high-light atoll and inner low-light lagoon) was 18.1 ± 1.1, 16.3 ± 0.8 and 7.0 ± 0.46 (mean % ± standard error), respectively. Of this cover, the relative contribution of key type I and II coral species was highly site specific. Coral abundance at Silhouette's granitic reef was dominated by *P. lutea* and *D. heliopora* but at the carbonaceous reefs of Desroches atoll by *P. lutea*; however, pocilloporids were also abundant. Importantly, the turbid waters of Desroches lagoon within the atoll were dominated by large colony sizes of the type I coral *A. formosa* and to a much lesser extent *P. lutea* (Fig. 4). Size frequency distribution of the *A. formosa* demonstrated that these lagoons contained colonies that certainly survived the 1998 El niño event. Growth rates used here were the maximum and minimum recorded growth rates for turbid waters (Crabbe & Smith 2005).

Discussion: Different species of coral appear to fall into groups that have either been susceptible to the 1998 bleaching event and only recently recruited (termed here as type I corals) or survived the 1998 bleaching event (termed type II corals). Combined with specific type I and II physiological responses, the community data provide clear evidence that several mechanisms shape the response of coral reefs to environmental variability.

Resilience— Of the key coral species tested here, acroporids and pocilloporids (our type I corals) are most susceptible to catastrophic ***acute*** thermal bleaching, a finding supported by other observations from the western Indian Ocean (McClanahan et al. 2007). Type I species are fast growing with large and successful reproductive output as opposed type II corals, which appear to reach large sizes despite slower growth rates: a clear sign that these species are resilient to periodic large changes in growth environment. Type I corals also appear to be more reliant on autotrophy as opposed to heterotrophy to sustain their metabolic needs for growth and cellular maintenance. Whilst this is obviously beneficial under 'optimal' reef building high-light environments this strategy is at a cost during extreme changes in temperature. Firstly, potential symbiont (autotrophic)-based mechanisms associated with bleaching, such as reactive oxygen production (Smith et al. 2005) will be greater where autotrophy per unit biomass of coral tissue is highest. Secondly, lower heterotrophy yields less potential to sustain metabolic demands for tissue re-growth and repair once autotrophy becomes compromised (Grottoli et al. 2006).

Alternative patterns of photosynthetic response from the elevated temperature experiment were observed for type I and II corals (Fig. 3) implying that at least two different forms of bleaching are evident. Likely, the two phenomena observed here both represent a complex composite of processes, which together can be used to describe discoloration of corals. Presumably, these phenomena may also operate in concert. Whether these phenomena are mutually exclusive in nature is debatable, in particular since our experiments here are obviously acute temperature exposure treatments, which are not necessarily representative of elevated temperature trends associated with El Niño warm water events; however, the alternative response to elevated temperature by the two coral types is consistent with the community data suggesting that the different 'bleaching' responses may inevitably prescribe the relative sensitivity to environmental change.

Refuge— Acroporids were highly sensitive to elevated temperatures yet remained the dominant coral genus in the turbid lagoons of Desroches. Here colonies were relatively large despite the lower growth rates that would be expected for the relatively low light environment (see Crabbe & Smith 2005). Temperature induced bleaching is moderated by light availability and so the observation would imply that these turbid waters offer refuge. Analogous findings have been reported for Alphonse Atoll (Iluz et al. 2008) where seagrass-based DOM release has reduced UV penetration and enabled 'type I' species to flourish. However, understanding the dominance by *Acropora* at Desroches is not so clear. It is possible that *Acropora* may have substantial potential to upregulate heterotrophy; however, this suggestion would assume that the elevated turbidity is from particulates that offer some organic enrichment to justify the energy invested in turning to heterotrophy. Alternatively, the low light environment may select against species with a lower P:R, i.e. those that are more heterotrophic, if the organic quality of particulates in the atoll was low. Unfortunately, the answer is not clear from the data available. In particular, the confounding nature of the type II coral *P. lutea* within the lagoon and of the type I coral *P. verrucosa* within the atoll cannot be explained.

Recovery— Our data suggest that Seychelles' reefs are in a stage of recovery. Percentage cover data are higher than those reported for 2004 (Linden et al. 2005). Such recovery is driven by physiological investment in growth and recruitment post 1998. Long term persistence of type I corals is driven by investment in high growth and fecundity; in contrast type II corals persist through investing into processes that regulate maintenance and physiological recovery (*tolerance*). Recruitment is a function of connectivity between reef units that act as refuge zones versus impacted zones. Whilst it is difficult to prescribe the relative contribution of recruitment of type I versus II corals, the small colony size of the fast growing acroporids and pocilloporids under 'optimal' growth conditions indicates that substantial recruitment must be accounted for by these less resilient species; furthermore, that some source for recruits must exist and be connected to the islands studied here. High recruitment was previously reported for the relatively remote Seychelles island of Aldabra (Stobart et al. 2005) suggesting that connectivity may not necessarily be a function of closely spaced reef units.

In summary, we have observed that Seychelles reefs are clearly susceptible to environmental stress beyond the thresholds for optimal growth but possess species that confer some level of tolerance. These reefs are still undergoing a phase of recovery towards pre-1998 conditions, as indicated by the relatively recent recruitment of type I corals (Fig. 1). Whether a 'true' pre-1998 community structure can ever return will of course depend on the subsequent frequency with which extreme environmental perturbations further act to 'crop' the more susceptible species and whether apparent refuges remain connected to other suitable growth environments. These refuges are often deemed to be sub-optimal growth environment for corals; however, our results demonstrate that these environments must have high conservation value.

Acknowledgements
We gratefully acknowledge The Mitsubishi Corporation for financially supporting this research. Also, extreme thanks to The Earthwatch Institute (UK), Seychelles Center for Marine Research and Technology (SCMRT), Seychelles Bureau of Standards, Nature Protection Trust of the Seychelles (NPTS), the Island Development Company (IDC) of the Seychelles and the Government of the Seychelles Republic for providing essential field logistical and administrative support, without which this work would not have been possible. A Royal Society (UK) Conference Grant was awarded to Suggett to attend the 11th ICRS and present this work.

What is the future for extensive areas of reef impacted by fish blasting and coral bleaching and now dominated by soft corals? A case study from Malaysia.

E. Wood, F. Dipper

Marine Conservation Society, Unit 3 Wolf Business Park, Alton Road, Ross-on-Wye HR9 5NB, UK.

Abstract. Reefs in the Tun Sakaran Marine Park, Sabah, have been damaged by fish blasting and also by coral bleaching and crown-of-thorns starfish. Coral communities comprising a mixture of growth forms and including a greater proportion of massive species are recovering better than those with a high proportion of laminar and foliaceous species. An example is at Kapikan Reef, a clear-water site where there were extensive stands of laminar *Montipora* on the shallow fore reef. Collapse of these colonies created rubble that has typically become colonised by soft corals, particularly *Xenia* spp, *Cespitularia* spp (Family Xeniidae) and *Clavularia* (Family Clavularidae). Fields of soft corals have been created, covering extensive areas and acting as a barrier to recruitment of hard corals. Lack of shelter, structural complexity and food in these areas is having a significant impact on fish populations. 71% of fish at the soft-coral-dominated site fell into the 0-5cm length category, and no fish over 15cm were recorded. At the control site, only 35% fell into the 0-5cm category, and individuals up to 35cm were recorded. Currently there are no signs of recovery to a hard-coral-dominated community on the Kapikan reef, and this has implications for biodiversity, reef growth and productivity.

Key words. phase shift, xeniid soft corals, resilience

Indroduction

Globally, coral reefs are in a state of decline, with those in South-East Asia showing some of the most serious losses and degradation ((Wilkinson, 2004). Problems include over-exploitation of reef resources, destructive fishing methods, pollution, disease, coastal development and coral mortality caused by ocean warming. One outcome of these impacts and disturbances can be loss and/or replacement of reef-building corals with other organisms. Reef-building corals are an essential component of healthy reefs, but there are an increasing number of reports of phase shifts from an ecological system where hard corals are dominant to those where non-reef-building organisms such as algae or soft-bodied cnidarians are dominant (Done 1992, Hughes, 1994, Chen and Dai 2004). A better understanding of the factors affecting resistance (ability to withstand impacts) and resilience (ability to recover) can help managers and other stakeholders decide on appropriate strategies and interventions that may help to stem further coral reef decline and promote recovery. This paper describes the response of reefs in Sabah, Malaysia to disturbances that have led to a phase shift from hard corals to soft corals, and have had a secondary impact on fish populations and biodiversity.

Materials and Methods

The Tun Sakaran Marine Park is situated off the south-east coast of Sabah, East Malaysia (Fig. 1). It was gazetted in 2004 and covers an area of 350 km^2. The reefs have been monitored since 1998 using rapid assessment techniques and quantitative surveys based on Reef Check methodology as described in Hodgson et al. 2006. A Reef Check monitoring site was first established on Kapikan Reef in 1998, and was re-surveyed in 1999, 2000, 2004 and 2007. Fish censuses were carried out on the same reef in May 2008 at sites dominated by soft corals, with a control site on the adjacent Mantabuan reef. For the fish censuses, counts were made along 10 belt transects, each 5m wide x 20m in length. Each 20m transect was split into 5-m sections and all specimens were recorded. Fish were identified to species where possible, or to family, and were assigned visually to size classes.

Results

The Kapikan reef is approximately 3.5km in length and has a gently-sloping profile. The shallow fore reef (1 – 5m depth) is up to 100m wide and has a very poorly developed spur and groove formation manifested as low undulations. The reef rim is not

M

well defined, but curves gently, with a slightly increased degree of slope below about 10m depth.

Figure 1. Location of study site: Tun Sakaran Marine Park. Kapikan reef (K) Mantabuan reef (M)

Hard and soft coral cover

Preliminary surveys along this reef in 1998 revealed areas of intact coral, with laminar and leafy *Montipora* and staghorn *Acropora* common, but with many other genera and growth forms present. Xeniid soft corals were widespread and common, sometimes forming patches many metres in diameter. In addition to the healthy stands of live coral, there were places where corals had been broken, probably as a result of fish blasting that is widespread in the area. In 1998, significant bleaching of hard corals due to an increase in sea surface temperature was noted on this reef, with as many as 30% of the colonies affected.

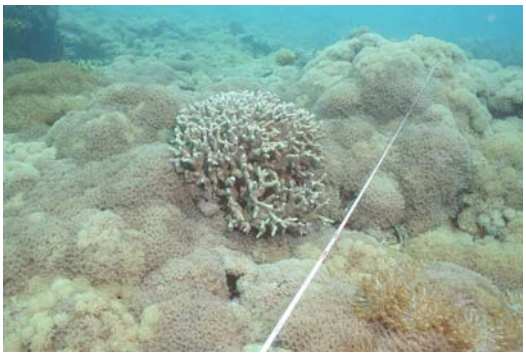

Figure 2. Kapikan reef 2007, heavily colonised by *Clavularia* and *Xenia* at a depth of 5m

Rapid assessments made along this reef annually since 1998 have revealed a gradual increase in the proportion of soft corals, and an expansion of the patches to form extensive fields (Fig. 2). The soft corals involved are *Xenia* spp, *Cespitularia* spp (Family Xeniidae) and *Clavularia* (Family Clavularidae). *Braireum* and *Efflatounaria* are also present, forming smaller patches. The soft corals have successfully colonised rubble, much of which on this reef consists of plates up to 15cm in diameter. Larger pieces of old coral and the tops and sides of scattered limestone blocks created by the death of massive corals on this reef have also mainly become colonized by the same assemblage.

Results from the Reef Check monitoring site established on this reef in 1998 show an upward trend in cover by soft corals on both the 4m and 9m depth transect. Soft corals were already well established on the shallow transect in 1998 (43% ±SE 2.68) and by 2007 cover had increased to 75.63% ±SE 2.43 (Fig. 3). On the 9m depth transect soft coral cover rose from 0.6% ±SE 0.25 in 1998 to 38.75% ±SE 2.25 in 2007.

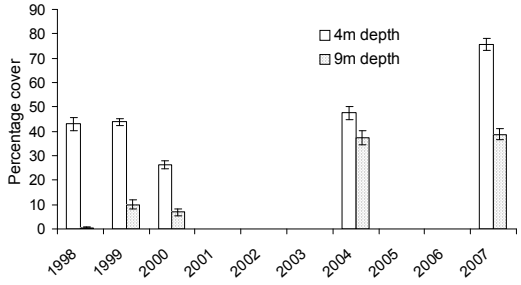

Figure 3. Percentage cover by soft corals at the Kapikan monitoring site

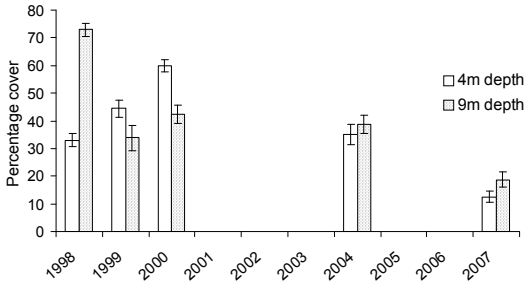
Live hard coral has fallen over the same period (Fig. 4). Hard coral cover on this reef could be declining for a number of reasons. Destructive fishing, crown-of-thorns starfish and bleaching have all been recorded and may be acting separately or synnergistically. During the first Reef Check survey in 1998 bleaching was in evidence, with an estimated 30% of colonies bleached at 9m and 10% at 4m



depth.

Figure 4. Percentage cover by hard corals at the Kapikan monitoring site

Damaged reefs in other parts of the Park show different responses. Rapid assessments over the same period, together with detailed information from 10 other monitoring sites, show that in many places where shallow-water coral assemblages dominated by *Acropora* and other branching corals have suffered damage, they have been reduced to smaller fragments of rubble. Unlike the larger rubble pieces on the Kapikan reef, these areas have not been colonized either by hard or soft corals.

In habitats where massive hard corals have died, there have been phase shifts to alcyoniids such as *Sinularia*, *Litophyton* and *Sarcophyton*, but this is not as comprehensive as the xeniid-*Clavularia* invasion seen on the outer reefs. Xeniids and *Clavularia* also occur on the inner reefs, but form discrete clumps rather than extensive fields.

Fish censuses

Fish counts were carried out on a typical section of the Kapikan reef dominated by xeniids and *Clavularia* and on a section of the adjacent Mantabuan reef where invasion by xeniids and *Clavularia* had not occurred. Both sites are subjected to similar levels of fishing.

Mean soft coral cover at the fish census site on Kapikan was 66.6% (± 7.94) in comparison with only 2.04% (± 0.65) at Mantabuan.. Conversely, mean hard coral cover was 3.6% (±0.99) at Kapikan and 46.62% (± 5.02) at Mantabuan. Both census sites had similar amounts of rubble (around 20%), but the Mantabuan reef had a greater proportion of rock (16.75% ±2.54) than Kapikan (2.85% ±0.85).

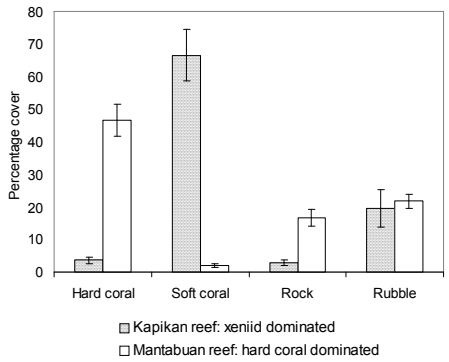


Figure 5. Main benthic components at the fish census sites

A total of 683 individual fish were recorded in the ten 5m x 20m transects on the xeniid-*Clavularia* dominated reef. Observations at the micro-habitat scale revealed that these fish were associated with rubble patches or clustered around the small number of surviving hard corals. Maximum fish length was 15cm, but the majority of fish (71%) were in the 0-5cm size category. The majority of these specimens were small labrid and pomacentrid species and mean density in the 11-15cm size class (the largest represented) was only 3/100m^2 (Fig. 6).

On the Mantabuan reef a total of 1,452 fish were recorded, of which only 35% were in the 0-5cm size category. 21% of individuals were in the 11-15cm size category (in comparison with 4.5% on the Kapikan reef) and the maximum size of fish recorded was 35cm. Representatives from all trophic levels and a wide variety of families were present on the Mantabuan reef, including lutjanids, pomacanthids, scarids, serranids and chaetodontids as well as labrids and pomacentrids. Mean density in the 11-15cm size class was 10 times higher (30/100m^2) than on the xeniid-dominated reef (Fig. 6).

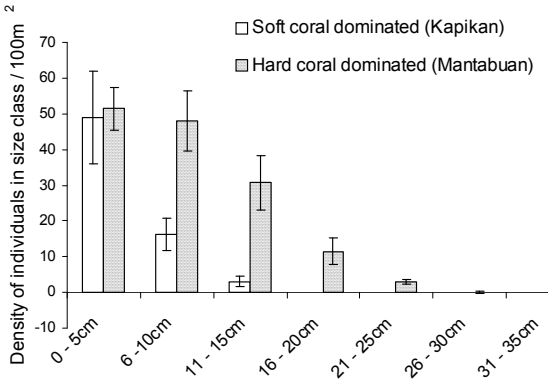

Figure 6. Density of fish recorded on the Kapikan (soft coral dominated) and Mantabuan (hard coral dominated) reefs according to size class.

Discussion

The reefs described in this paper are situated within the Tun Sakaran Marine Park, which was gazetted in 2004 and is currently the largest MPA in Malaysia. The Park lies within the coral triangle and the reefs are of value for their high biodiversity, natural resources and recreational interest. However, like many others in the region, they have been damaged and degraded, particularly by destructive and over-fishing, coral bleaching and predation by crown-of-thorns starfish.

Although the relative contribution to reef decline from each of the different impacts/activities has not been quantified, one of the outcomes at some sites has been a phase shift from hard corals to a predominately xeniid-*Clavularia* assemblage. This

particular community change has developed only on the gently-sloping eastern-facing outer reefs where the water is clearest, and where laminar hard corals (primarily *Montipora*) had been common. When these corals collapsed they produced relatively large pieces of rubble that acted as suitable 'settlement plates' for xeniids and their allies. The tops and sides of scattered limestone blocks created by the death of massive corals on these outer reefs have also mainly become colonized by the same assemblage.

Xenia, Cespitularia, *Clavularia* and related forms are well know for their ability to colonise vacant space on reef surfaces, and can spread rapidly by cloning where conditions are suitable (Fabricius and Alderslade, 2001). It appears from this study that the combination of clear water, gentle slope and a disturbed but sufficiently stable substratum on the Kapikan outer reef has given xeniids a competitive advantage over other organisms. Their strategy of larval brooding and effective asexual propagation enables fast clonal growth (Fabricius and Aldersade, 2001) and their success is further enhanced by their ability to produce allelopathic substances that chemically inhibit growth and survival of other organisms (Sammarco et al, 1983, Fabricius and Alderslade, 2001).

Damaged reefs in other parts of the Park show different responses. In many places, shallow-water coral assemblages dominated by *Acropora* have been reduced to smaller fragments of rubble that have not, as yet, been colonized either by hard or soft corals. These reefs experience similar tidal current and wave exposure to the xeniid-*Clavularia* dominated reefs, but the fragments are probably too unstable to allow colonisation. Where stable limestone blocks remain, alcoynid soft corals belonging to the genera *Sinularia* and *Sarcophyton* are typical colonists. Xeniids occur, but do not form the extensive fields seen on the outer reefs. Similar habitat preferences have been described for the Great Barrier Reef, where alyconiid 'invasions' are associated with disturbed nearshore reefs (Fabricius, 1998) while xeniids invade outer shelf sites (at > 3m depth). In the latter cases, however, the dominant genus was *Efflatournaria*, and the patches were reported to be not larger than tens to hundreds of square metres.

In Komodo National Park (Indonesia) large fields of the soft coral *Xenia* often grow on top of rubble created as a result of fish blasting (Fox et al. 2003). The genera *Sarcophyton*, *Nepthya* and *Clavularia* are also present in these *Xenia* fields.

Phase shifts to cnidarians other than alcyoniids have been reported from a number of locations, and mainly involve coralliomorphs (Kuguru et al. 2004; Tkachenko et al. 2007; Work et al. 2008). A shift to domination by the sea anemone *Condylactis* has been reported from southern Taiwan (Chen and Dai, 2004) following pressure on reefs over two decades from overfishing, coastline development and tourism.

The fields of xeniids now colonizing large sections of the Kapikan outer reef have created an impenetrable blanket that provides few hiding places or feeding grounds for fish. The fish that are present are mainly small species of labrid and pomacentrid that are associated with isolated patches of rubble or small rocks and corals within the xeniid-*Clavularia* fields. This represents a significant reduction in value of the reef for biodiversity, local fisheries and tourism.

The fact that few large fish were recorded even at the hard coral dominated sites could be related to the relatively short transect lines (20m). However, numerous fish surveys conducted throughout the Park using 50m transects confirm that large fish are very scarce. Mean density of reef fish such as groupers and rock cod, snappers, emperors and sweetlips at 12 monitoring sites recorded annually since 1998 has typically been less than one individual per family per100m^2, and at several sites has been zero (Wood, 2008). The reefs in the Park have been heavily fished for decades using hook and line, nets, traps and explosives, so it is not surprising that fish density is low and sizes are small.

The ability of the reef to recover from this phase shift is unknown, but it appears that currently the xeniids are successfully competing with the remaining live hard corals in addition to spreading actively over damaged areas. Thus they are not only forming a physical blanket preventing settlement and recruitment of hard corals, but they are also killing those that remain.

Experimental work has shown that reefs exhibiting a phase shift to algal dominance can recover in situations where herbivorous fish are abundant (Bellwood et al 2006; Hughes et al 2007). However, a parallel scenario is unlikely to exist for xeniids because they have few natural enemies. The only reason why they might die back is from senescence or from mortality as a result of bleaching or physical disturbance (e.g. storms).

Xeniids are known to be susceptible to bleaching (Fabricius and Alderslade 2001) but hard corals are also affected and so a warm water event would most likely cause die-back of both soft and hard coral communities. It is possible that storms could result in the rubble and/or soft corals being dislodged, although wave action is not an important modifying factor at this location. The east coast of Sabah is outside the hurricane zone, and severe storms are relatively infrequent. If the underlying rubble was again 'laid bare' as a result of storms or die-back of the xeniids due to bleaching there is no

certainty that hard corals would prevail over soft corals when re-colonisation occurred.

It is difficult to predict what, if any, management interventions might be effective in enhancing the ability of the reefs to revert to hard coral domination. It has been shown that phase shifts to algal domination can be prevented or dramatically slowed down by the grazing of herbivorous fish. Thus a management 'insurance policy' to prevent such phase shifts from occurring is to manage fish populations so that over-fishing of large herbivores such as scarids and labrids does not occur. However, in the absence of effective soft coral 'grazers' it is difficult to know what options exist for managing xeniids and their relatives.

Experimental work on soft coral fields in the Komodo National Park (Fox et al 2003) showed that small hard corals were present beneath the soft coral canopy and 'fared much better' if the soft coral was removed. In addition, hard corals recruited to the cleared rubble, resulting in an increase from an average of 2.94 colonies per m^2 when the soft coral canopy was first cleared to an average of 7.15 colonies per m^2 after 6 months. In another experiment, Fox et al showed that *Acropora yongei* nubbins attached to PVC pipes and elevated 5-10cm above the soft coral canopy survived better than nubbins that were at the same level as the canopy. Survival was 70% after 6 months for the elevated nubbins in comparison with 30% for the nubbins in the canopy. The researchers concluded that soft corals inhibited recruitment, growth and survival of hard coral over the short term but suggested they could facilitate hard coral recovery in the long term. This is because the soft corals stabilise the rubble, and if gaps open up, hard corals may successfully settle in these more stable patches. It would be useful to carry out similar trials at the study site in Sabah to see if clearance of patches within the *Xenia* fields leads to an increase in hard coral cover.

In conclusion, human activities and impacts have changed the ecological character of the Kapikan reef from a reef-building to a non-reef-building state, and this altered ecology currently shows no sign of reverting back. Continued studies will determine whether or not the xeniid-*Clavularia* assemblage is a climax community, or whether this set of dominant organisms will be replaced by another or even revert to hard corals. Recovery might occur if the soft corals die back or are torn away by storms, and it is possible that clearance of patches within the *Xenia* fields could be beneficial.

It is anticipated that increased surveillance and enforcement in the area will lead to a reduction in fish blasting and that this will prevent more sections of the reef being reduced to rubble. It is vital that remnant populations of hard coral remain healthy because they will provide a source of coral larvae that could aid recovery of damaged areas.

The maintenance of reef islands

D.E. Hart

Department of Geography, University of Canterbury Te Whare Wananga o Waitaha, Private Bay 4800, Christchurch 8020, New Zealand

Abstract. Low coral reef islands are known to comprise biogenic sediments but the processes whereby these islands are nourished are poorly understood. This paper argues that the sediment system of large reef platforms can be strongly compartmentalised, at sub-kilometre scales, so that contemporary island maintenance and growth depends on organisms and processes operating within a small physiographic and ecological sector of the reef flat. Evidence is provided through a study of the origins and pathways of island-nourishing sediments on Warraber Reef, using textural, compositional and selected dating analyses of surface sediments. Results reveal that the mollusc-algae covered sand flats of the emergent, inner reef flat are the dominant contemporary source of island sediment. In contrast, deeper, more-distant and leeward reef-flat zones are functionally isolated from the island beach deposit. This is despite the order of magnitude greater productivity, more-frequent submergence, and more-energetic wave environment of the latter areas, but in-line with reef flat sediment transport directions and the proportionately-greater particle production rates of organisms living in the windward, near-island zones. The key findings of this study are summarised in a theoretical model of the source-to-sink journey of skeletal biogenic sediments in low island environments, which is applicable to reef-island management.

Key words: Reef islands, Carbonate sediment, Platform reef, Reef flat.

Introduction

By 2015 half the world's population will live in coastal zones, including on low coral reef islands. These reef-surface features are described as particularly vulnerable to changing environmental conditions such as sea level rise (Woodroffe et al. 2007). They are constructed of accumulations of biogenic sediment primarily from the surrounding reef platform (Hart and Kench 2007). Beaches form the crucial interface through which these islands are nourished, built and eroded with reef platform sediments.

Little detail is known about the relationship between the different bio-physiographic zones of reef platforms and the ultimate nature of island sinks. A number of seminal papers have demonstrated that the character of reef sediments depends on: the carbonate producing and eroding organisms present (Stearn *et al*. 1977, Scoffin *et al*. 1980, Scoffin 1987); the contributing organisms' skeletal structure (Scoffin 1992, Ginsburg *et al*. 1963, Chave 1964, Enos and Perkins 1977); and on their interaction with biological, physical and chemical processes of breakdown and transport within reef environments (Folk and Robles 1964, Maiklem 1968, Gourlay 1988).

This paper contributes to this discourse through an investigation of how spatial variations in sediment processes across large reef platforms can influence the nature of a low-island beach. Comparisons between beach and reef-flat deposits reveal functional relationships between the island sink and reef sources for Warraber Reef, an intertidal platform in central Torres Strait, Australia. The differing spatial and organism contributions to contemporary beach nourishment found are used to model the functioning of reef sediment systems and discuss their importance in understanding reef island futures.

Study Site

A large platform (11 km^2) and small, oval-shaped sand cay (1.1 km^2) form the Warraber Reef system (Fig. 1). Warraber is middle of 3 platforms called The Three Sisters, situated at the northern end of the Great Barrier Reef in central Torres Strait (10°12'S, 142°49'E). The Strait is characterized by 3.5 m spring tides, tidal currents up to 4 ms^{-1}, and a monsoonal wind and wave regime. Strong winds from the southeast (~15 ms^{-1}) dominate the dry season (March-Sept) while weaker northwesterlies (0-5 ms^{-1}) occur during the wet season.

Warraber (or Sue) Island stands 2 to 8 m above mean sea level (MSL) on the northwestern reef platform. It is thought to have developed incrementally over the last 3500 years while the reef surface (0.5 to 2.3 m above MSL) and much of its outer structure grew during the Holocene, around a Pleistocene reef core (Woodroffe et al. 2007). Rimmed by a young coral-algal rim, the platform's

contemporary reef flat has two distinct areas: the large, elevated central and eastern section with sand flats covering fossil microatolls and branching corals; and the smaller, lower, western reef flat characterized by muddy-sand flats near the beach and coral patches separated by sand channels towards the rim. The boat channel, constructed in 1991, divides the western reef flat in two. On low tides more than half of the reef flat drains fully while water ponds across deeper, western and outer-eastern, areas.

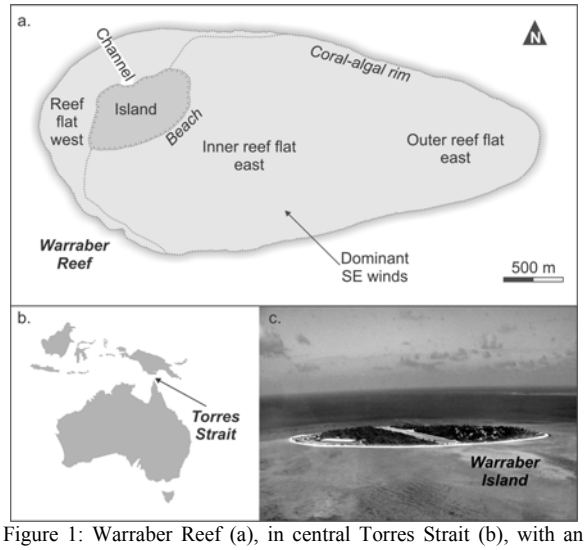

Figure 1: Warraber Reef (a), in central Torres Strait (b), with an oblique aerial photograph from the south side of the island (c)

Material and Methods

218 surface sediment samples were hand scooped along 15 beach to inner reef flat profiles and 5 transects radiating out from the island to reef rim. 3 additional samples were dredged from the boat channel at 11 m below MSL. Samples were cleaned of organic matter, and the fines were removed by wet sieving (particles <0.063 mm). The remainder was split into 15 and 70 g subsamples.

The 70g subsamples were settled through a 6.5 m long water column into a collection core, which was then separated into 4-6 visually-distinct fractions (after Kench and McLean 1996). 100 grains were grid-sampled from each fraction and their constituent origins determined using a reflected-light binocular microscope. Constituent weights were summed across all fractions to determine their % in each sample. For constituents comprising >1% of samples, Wilcoxon rank-sum tests were used to determine if variation between the beach and reef flat sample groups was significant (Zar 1999). Agglomerative, hierarchical cluster analysis was performed on the complete sample constituent data using the *S-Plus* software programme *Agnes* (Everitt 2002) and the sample constituent clusters mapped across the reef platform.

The 15 g subsamples were settled through a rapid sediment analyzer. Sample settling distributions and statistics were calculated using Middleton's (1967) negative $\log_2$ Psi parameter (ψ) and Folk's (1965) graphic formulae. Cluster analysis was performed separately on the textural data using *Agnes* and the textural cluster trends mapped across the reef flat.

Results

Table 1 shows the main constituents (≥1%) that made up the reef flat and island beach sediments. The commonest sediment constituent was mollusc (mostly gastropod), comprising 55% and 35% of beach and reef-flat samples respectively. The next commonest constituents were coralline algae (16-26%, mostly encrusting) and coral (8-13%). On the beach this was followed by *Halimeda* (7%), foraminifera (5%), and fragments of beachrock (2%) while on the reef flat, the fourth commonest constituent was foraminifera (10%), followed by *Halimeda* (8%), crustacean (4%), and vermetid mollusc (2%).

Amounts of the two main constituents, mollusc and coralline algae, were significantly different (P>0.01) between the beach and reef flat sample groups. Of the less-common constituents, beach and reef-flat sediments contained differing amounts of foraminifera, crustacean and beachrock material but significantly similar amounts of coral, *Halimeda* and vermetid mollusc. The mean sediment compositions reveal that, on average, the beach comprised more mollusc and beachrock fragments while the reef flat had more coralline algae, foraminifera and crustacean sediment than occurred on the beach (Table 1).

Table 1: Variation in the mean constituent composition of beach versus reef flat (RF) sediments (* indicates P<0.01 in Wilcoxon rank-sum variance tests). Reef flat cover and carbonate production are included for comparison, where cover represents the 24% of the reef flat occupied by carbonate producers (Hart and Kench 2007)

Organism type	Mean % sediment composition		Mean % of live cover	Mean % of carbonate
	Beach	RF	RF	RF
Mollusc (gastropod)	54.9* (47.7%)	34.8* (27.8)	3 -	4 -
Coralline algae (encrusting)	15.6* -	25.6* -	47 (46.5)	18 (16.2)
Coral	8.2	13.1	43	74
Halimeda	6.9	8.4	6	1
Foraminifera	4.8*	10.2*	1	2
Vermetid mollusc	0.6	1.5	<1	<1
Crustacean	0.6*	3.5*	<1	<1
Beachrock fragment	1.9*	0*	-	-

Comparisons between these sediment results and reef flat ecology data from Hart and Kench (2007) reveal that, on average, *Halimeda* and the minor constituents (<4%) were represented in the two sediment sinks in similar proportions to their reef flat cover and/or carbonate budget contributions (Table 1).

However, the occurrence of the other, major constituents in the sediments contrasted their parent organisms' reef flat cover and carbonate productivity. Coral, and to a lesser extent, coralline algae, appear to be under-represented as sediment constituents, while molluscs and, to a lesser extent, foraminifera appear over-represented, relative to their reef flat cover and productivity. In order to investigate explanations for these differences, surface-sediment spatial patterns were mapped based on the cluster analyses of % constituent compositions, and the textural properties.

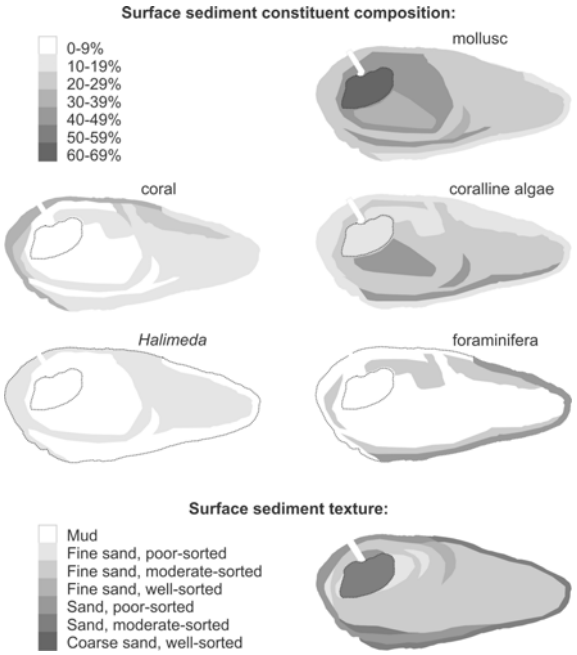

Figure 2: Trends in the concentrations of the five main sediment constituents in the beach deposit, represented by the island shape, and across the reef flat (top); and corresponding textures (bottom)

Fig. 2 shows that mollusc sediment concentrations generally increased from deeper-outer areas, towards central-emergent areas of the reef flat, and were greater in the beach deposit than anywhere on the reef flat. Almost the exact reverse pattern was evident for coral sediments. Coralline algae content decreased gradually south to north across the reef flat, and between the reef flat and beach deposits. *Halimeda* constituents were slightly more concentrated in deeper reef flat areas compared to on the beach and inner, emergent reef flat. The concentration of foraminiferal tests was high around the eastern and southern reef rim and patchy across the rest of the platform. Fig. 2 also reveals that sediment texture was coarser and better-sorted in the beach deposit and on the reef rim, relative to across most of the reef-flat surface. The boat channel sediments were dominated by poorly-sorted mud of indistinct origin.

Discussion

Two key results requiring explanation are that Warrraber beach appears to contain disproportionally high concentrations of mollusc sediment and low amounts of most other constituents.

Textural results revealed the island shore as a high-energy setting relative to much of the surrounding reef flat. Mollusc shells are ideally suited to transport to, and retention within, such a deposit as they are buoyant and transportable as well as durable compared to the majority of other reef constituents (Chave 1964, Force 1969). Further, for most molluscs on Warraber (which were small gastropods) the translation of live-parent organisms into sediment particles suitable for nourishing the beach simply entails death. This contrasts coral and encrusting coralline algae, which require the additional step of skeletal breakdown to form particles suitable for beach nourishment.

The dominance of mollusc in the beach deposit is also due to the concentration of suitable mollusc sediments on the inner reef flat surrounding the island (Fig. 2). This corresponds to a concentration of live molluscs in this area (Hart and Kench 2007). Dating of individual particles by Woodroffe et al. (2007) reveals that molluscs form the youngest fractions of Warraber's island and reef-flat deposits, aged between modern and 2700 y, supporting the idea of a link between contemporary mollusc production on the inner reef flat and the concentration of mollusc sediment in the island beach.

Like molluscs, foraminifera have tests that are highly-transportable, durable, and simply translated into sediment upon death of the parent organism. Unlike molluscs, however, they form the oldest constituents in Warraber's island and reef-flat deposits (6600-4500 y old, Woodroffe et al. 2007). This indicates that, while foraminiferal material can persist in this reef environment, there may have been a decrease in the generation of new material over time. Today most foraminifera live far from the island on the reef rim, with a few living nearshore, east of the island (Hart and Kench 2007). This live-assemblage pattern is similar to the observed foraminiferal sediment pattern (Fig. 2). Accordingly, the slightly-lower average concentration of foraminifera in the beach relative to reef-flat sediments found in this study (Table 2) is explained by the location of concentrated foraminiferal sediments either far or up-drift from the island shore (according to the dominant-southeasterly wind wave regime) as well as by the dilution of the beach constituents with the abundant mollusc material.

The proportions of *Halimeda* and coral constituents in the island beach reflect their average concentration in reef flat deposits (Table 2). *Halimeda*'s role in the

sediment budget reflects its minor role as a reef flat cover type and in carbonate productivity. This is not the case for coral, which was shown by Hart and Kench (2007) to be the second commonest live-carbonate-producer cover type and, by far, the dominant carbonate producer. Reasons as to why this extensive coral cover and carbonate production does not translate into dominant sediment contributions in either the reef-flat or island deposits include, first and foremost, that even in this emergent-platform environment, the bulk of coral carbonate produced is retained within the reef framework upon tissue death and not broken into sediment particles. Coral only grows where there is accommodation space. On Warraber, coral growth is concentrated in outer-reef-flat and reef-rim environments, where there is horizontal and vertical accommodation space respectively. Also, when coral skeletons do break down, their skeletal architecture, in combination with bioerosion processes, commonly leads to the production of a bimodal sediment population: that is, gravels which are readily worn into silts and muds (Scoffin 1987). The former are ill-suited to transport across the reef flat to the island shore, particularly from the western areas (where coral sediments are most concentrated) as this is against the dominant wave regime. The latter, fines cannot be retained in the high-energy, coarse beach deposit (Fig.2).

The path of coralline algal sediment generation is slightly different again. This carbonate producer is the most-extensive living-cover type on Warraber Reef, after the non-carbonate producing brown algae (Hart and Kench 2007). But this cover translates into to far-less carbonate per unit live cover than for coral, so that there is less coralline algal material available for potential sediment generation. Compared to its role in the carbonate budget, coralline algae makes up a slightly-greater proportion of the reef flat, and slightly-smaller proportion of the island-beach, sediment budgets. Its reef-flat sediment contributions may be explained by its consistently-high cover across the reef flat, including growth on existing sediment particles - characteristics which predispose it to key sediment contributions. The slightly lower concentration of coralline algae in the beach may, in turn, be the product of winnowing of this not-so-durable constituent (Chave 1964).

Implications

The International Coral Reef Symposium (ICRS 2008, 3) scientific outcomes overview states that recent evidence indicates tropical reef systems are “primarily connected at scales of tens of kilometers”. This comes from a biological perspective and is counter to pervious beliefs that reefs are highly interconnected at scales of thousands of kilometers. The present research suggests that low-reef islands are connected to reef ecosystems at even-more-local scales. That is, in terms of beach nourishment (and thus island-building), the sediment system of the large, emergent Warraber reef platform is highly compartmentalized in space and time. The most-important beach constituent (mollusc) is largely locally (<1 km) and recently (≤2700 y) produced while the dominant carbonate producer (coral) and live-cover types (brown algae, coralline algae, coral) on the wider reef platform contribute far less to the maintenance and development of the contemporary island shore.

Based on these findings, Fig. 3 outlines the source-to-sink journey of skeletal biogenic sediments in low island environments. This model combines carbonate and sediment-particle production stages with the morphodynamic concept of low islands as the product of reef-flat sediment transport and nodal-point deposition. It shows that reef platform deposits, including cays, are inextricably linked to their surrounding ecosystems, and that this relationship is highly compartmentalized via the complex set of biological and physical processes involved in the creation, alteration and transport of reef and reef-island sediments.

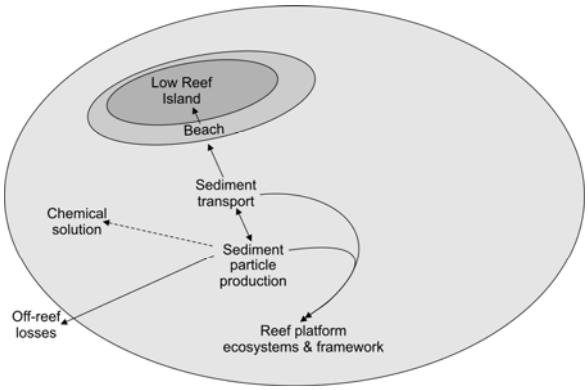

Figure 3: Theoretical schematic of a reef island sediment system, including carbonate production in surrounding platform ecosystems; its translation into sediment via producer-organism death and/or biological or mechanical erosion; and sediment transport to the beach for island nourishment and development, deposition in the reef edifice, or losses offshore and via chemical solution.

Current models indicate that reef-flat widths, elevations, current strengths and directions, and sediment volumes are all important in determining the rate and nature of island development (e.g. Gourlay 1988, Kench and Brander 2006, Barry et al. 2007). These factors are largely outside of the control of reef managers. The model developed in this study indicates that the amounts, and constituent and textural natures, and spatial distributions of sediments produced in reef flat environments today are crucial in

determining the island-beach sediment budgets and, thus, island maintenance, development or erosion. One major implication of this model is that it is necessary to understand the carbonate and sediment production systems of reefs in order to understand the future of their islands under changing environmental conditions such as those brought about by climate change, increased pollution and resource pressures. On Warraber, the reef-island sediment budget depends on production by a limited set of organisms, across a limited area of reef surface. The particular organisms and reef flat zones responsible for island maintenance will differ from reef to reef and change over time - establishing these locally can help reef managers to forecast the future of islands and empower them with information about the importance of conserving particular reef-flat ecosystems for island maintenance.

Coral recruits to settlement plates at remote locations in the U.S. Pacific

J. C. Kenyon

Joint Institute for Marine and Atmospheric Research, University of Hawaii, 1125B Ala Moana Boulevard, Honolulu, Hawaii 96814, U.S.A.

Abstract. Documenting the density and taxon of coral recruits to settlement plates is a widely used method of quantifying coral recruitment. Four deployments of recruitment plate arrays were made at six locations in the Northwestern Hawaiian Islands at annual or biennial intervals between 2001 and 2006. Similar arrays were deployed at Kingman Atoll, Palmyra Atoll, Baker Island, and Rose Atoll for three consecutive, 2-year periods and at Jarvis Island for one, 2-year period. Most locations with multiple deployments showed temporal variability in the density of coral recruits. In the Northwestern Hawaiian Islands, lowest average recruitment rates (8.5 and 10.4 recruits m^{-2} yr^{-1}) were found at Midway and Pearl and Hermes Atoll, respectively, and highest average rates were found at Maro Reef (265.3 recruits m^{-2} yr^{-1}). Annual rates at the five remote central Pacific locations ranged from 0.8 to 16.3 recruits m^{-2} yr^{-1}. The taxonomic composition of the recruits did not reflect the composition of adult coral communities. These results reveal the need for further study of coral reproductive and recruitment processes in these remote areas where little data have been collected.

Key words: corals, recruitment, settlement plates

Introduction

The reported decline of coral reefs (e.g., Pandolfi et al. 2005) necessitates improved understanding of their intrinsic capabilities for replenishment. The capacity of scleractinian corals to maintain or renew genetically diverse populations through sexual reproduction is a key attribute of reef resilience (West and Salm 2003). Recruitment patterns can be an important factor affecting the future coral community (Coles and Brown 2007).

Documenting the density and taxon of coral recruits to settlement plates is a widely used method of quantifying coral recruitment (Mundy 2000). Recruitment studies involving artificial substrata are typically conducted at locations readily accessible from land-based institutions, and the substrata are submerged for several months (e.g., Polachek, 1978; Fitzhardinge, 1985; Kolinski 2004). Studies from more isolated regions that are distant from supportive land bases are rare (e.g., Hughes et al., 1999).

The Northwestern Hawaiian Islands (NWHI) are a chain of small rocky islands, atolls, coral islands, and reefs that span ~1800 km over more than five degrees of latitude in the northwestern portion of the Hawaiian Archipelago (Fig. 1). Designated as Papahānaumokuākea Marine National Monument in 2006, they are uninhabited except for seasonal field camps or small maintenance crews at several locations. Given the expanse of the region, most marine research activities require support from large institutional research vessels.

Situated closer to the equator but spread across more than 5×10^6 km^2 of the tropical Pacific Ocean are five small islands/atolls (Kingman Atoll, Palmyra Atoll, Jarvis Island, Baker Island, Rose Atoll; Fig. 1) that are managed by the U.S. Fish and Wildlife Service. As in the NWHI, research is largely conducted aboard large research vessels.

No previous studies of coral recruitment have been conducted in any of these locations. A pilot study was launched in the NWHI in 2001 to examine spatial and temporal variability of the density and taxonomic composition of coral recruits at six locations by attaching settlement plates to the anchors of oceanographic instruments. Similar methods were applied to the five remote central Pacific locations beginning in 2002. This paper, which presents the results from a 5-year study in the NWHI and a 6-year study in the remote central Pacific locations, is a first look at coral recruitment in these locations.

Material and Methods

An array ("cohort") of 16 (15 cm × 16 cm) unglazed terra cotta plates was deployed at six locations in the NWHI (French Frigate Shoals, Maro Reef, Lisianski, Pearl and Hermes, Midway, and Kure) and five remote locations in the central Pacific (Fig. 1) for consecutive periods of ~1 or 2 years. At the end of each deployment period, the entire submerged array

and plates were retrieved and a new array with fresh plates was deployed on the same day.

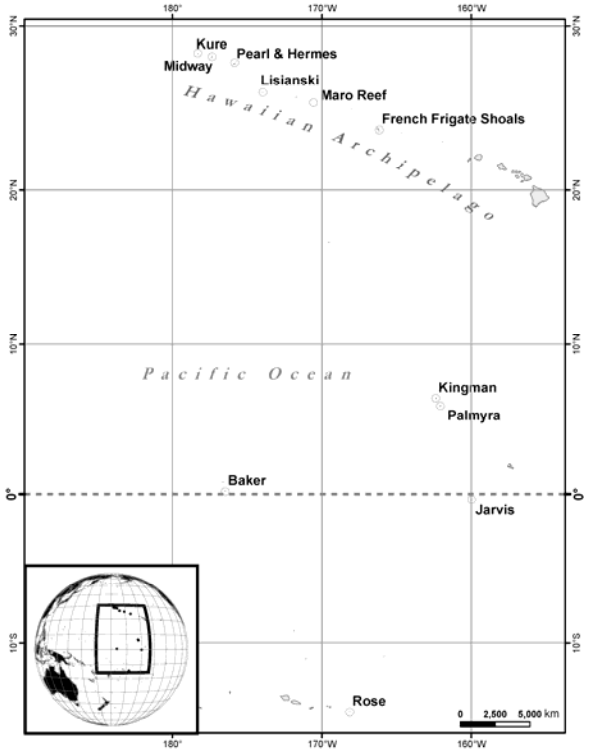

Figure 1. Deployment locations of settlement plates.

The plates were assembled in a framework of polyvinyl chloride (PVC) pipe in which grooves had been cut to hold the plates. Arrays deployed at < 10 m depth were attached with cable ties to the anchor of an oceanographic buoy. A sheltered site was selected to moor the buoy and arrays, where they might withstand the long deployments. At Baker and Jarvis Islands, there was no suitable protected shallow-water (<10 m) habitat in which to deploy a surface buoy. Instead, the PVC framework with plates was attached to an anchor in deeper water (~ 15–20 m). Of the 16 plates, 8 were placed horizontally and 8 vertically.

After retrieval, the plates were rinsed of excessive sediment and algae, frozen, and returned to Honolulu. Both sides of each plate were examined for coral recruits with a dissecting microscope. Recruits were classified in the family Pocilloporidae, Acroporidae, Poritidae, or unidentified based on skeletal criteria of Babcock et al. (2003), with the exception of the first cohort from the NWHI when this diagnostic reference was not available. Density of recruits (no. m^{-2}) was calculated based on the number of retrieved plates and the available settlement surface area of each plate. In calculating annual recruitment rates (no. m^{-2} yr^{-1}), densities were normalized to the number of days the arrays were deployed at each location.

Results

Northwestern Hawaiian Islands

Most locations showed temporal variability in the annual rates of coral recruitment (Fig. 2a). At all locations, the annual recruitment rate on plates deployed from 2004 to 2006 was substantially less than that of previous cohorts. The highest average annual recruitment rate (265.3 recruits m^{-2} yr^{-1}) was found at Maro Reef, and the lowest average annual rates (8.5 and 10.4 recruits m^{-2} yr^{-1}) were found at Midway and Pearl and Hermes Atolls, respectively.

Of the 891 recruits tallied on plates from the second, third, and fourth cohorts, 96.2% belonged to the family Pocilloporidae, 2.7% to the Acroporidae, and 1.1% to the Poritidae (Fig. 2b).

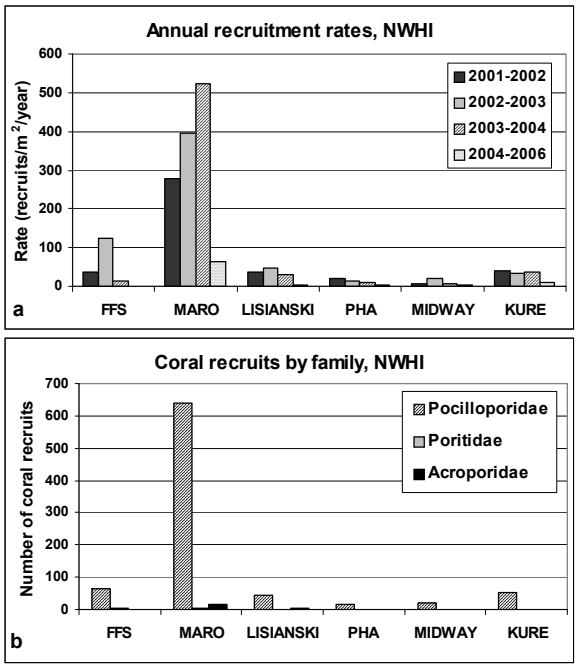

Figure 2. Coral recruitment parameters from settlement plates in the NWHI between 2001 and 2006. a. Recruitment rates (no. m^{-2} yr^{-1}). b. Taxonomic composition by family. FFS = French Frigate Shoals; PHA = Pearl and Hermes Atoll

Remote Central Pacific Locations

At Jarvis Island, the entire first cohort of plates had become detached from the anchor and was not found, presumably due to the high wave energy environment. Only 9 of the 16 plates from the second cohort were recovered; hence, a third array of plates was not deployed at Jarvis. There was temporal variability in annual recruitment rates at Kingman Atoll, Palmyra Atoll, and Baker Island (Fig. 3a). At Rose Atoll, only one coral recruit was found from all three, 2-year deployments. The highest average annual rate (8.1 ± 2.8 recruits m^{-2} yr^{-1}) was found at Kingman Atoll and the lowest average annual rate (0.3 ± 0.2 recruits m^{-2} yr^{-1}) was found at Rose Atoll. The highest average

annual rate in the remote central Pacific locations was lower than the lowest average annual rate in the NWHI, at Midway Atoll.

Of the 68 coral recruits found from all remote central Pacific locations, 25.0% belonged to the family Pocilloporidae, 20.6% to the Acroporidae, 32.4% to the Poritidae, and 22.1% could not be identified. The relative contribution of each taxon varied by location (Fig. 3b). At Kingman Atoll and Baker Island, the dominant component of the recruiting taxa also varied by cohort. At Kingman Atoll, acroporids dominated the first cohort (80% of recruits, n = 10) but poritids dominated the final cohort (90% of recruits, n = 20). At Baker Island, pocilloporids were exclusively found in the first and second cohorts (i.e., 100% of recruits, n = 7, 4, respectively) but acroporids dominated the third cohort (42% of recruits, n = 12). At both Kingman Atoll and Baker Island, settlement plates were deployed and retrieved at comparable times of the year.

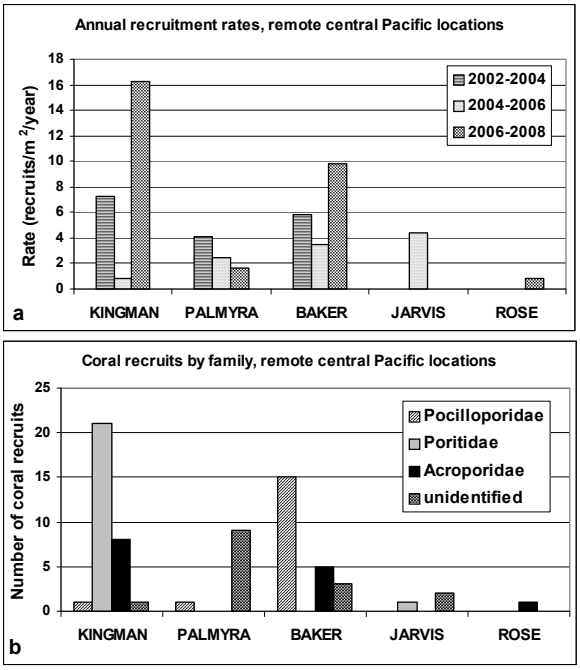

Figure 3. Coral recruitment parameters from settlement plates at remote central Pacific locations between 2002 and 2008. a. Recruitment rates (no. m^{-2} yr^{-1}) b. Taxonomic composition by family.

Discussion

Northwestern Hawaiian Islands

At each location the placement of the anchor to which the plates were attached was based on protection by neighboring reef structure from severe wave activity. Consequently, the arrays were deployed in varying geomorphological habitats with variable live coral composition of adjacent reef. These habitat variations preclude statistical comparison among locations in recruitment rates or taxonomic composition.

Kenyon (1992) determined that three species of *Acropora* are sexually mature at French Frigate Shoals from June to August, but no other studies of coral reproduction exist from the NWHI. It is reasonable to assume, however, that the mode and timing of gamete or planula release is similar to that displayed by conspecifics in the main Hawaiian Islands (MHI). With the exception of the 2003–2004 cohort, settlement plates were deployed in September and October, towards the end of the reproductive periods displayed by the suite of spawning taxa (Kolinski and Cox 2003), and likely missed the peak larval settlement period of that year. The 2003–2004 cohort, which was deployed in July and August, provided settlement substrate during more peak reproductive periods, which may account for the higher densities of that cohort at Maro Reef (Fig. 2a).

The taxonomic composition of the recruits was disharmonic with the composition of the adult coral communities in this region. The genus *Porites* dominates at all islands/atolls in the NWHI both in terms of percent cover and colony density (Kenyon et al. 2006; 2007a,b), but only ~1% of coral recruits were poritids. In contrast, pocilloporids made up >96% of the recruits although their contribution to percent cover ranges from 3.5% at Maro Reef to 33.1% at Kure Atoll (J. Kenyon, unpubl. data). Year-round release of planulae by *Pocillopora damicornis* (Kolinski and Cox 2003) may contribute to the disharmonic representation of this genus in the coral recruits. The contribution of adult acroporids to percent cover ranges from 1.5% at Laysan (Kenyon et al. 2007b) to 21.6% at Kure (J. Kenyon, unpubl. data) but only 2.7% of all the recruits were acroporids. In a 2-year study of recruitment in Kaneohe Bay, Oahu, in the MHI, Fitzhardinge (1985) observed that there was no obvious relationship between the abundance of adult colonies at a site and the number and taxonomic composition of the recruits. In a 24-year study of visible (> 0.5 cm) recruits at four sites off Kahe Point, Oahu, Coles and Brown (2007) also noted that *Pocillopora meandrina* generally had higher recruitment rates than *Porites lobata*. Nonetheless, the extreme paucity of poritid and acroporid recruits in the present study highlights the need for better understanding of coral reproductive, recruitment, and early life history processes in this region, and has important implications for recolonization by larvae should populations of these taxa be negatively impacted by natural or anthropogenic disturbances.

At all locations, annual recruitment rates calculated from the 2004–2006 cohort were lower than those of previous cohorts; this decrease was especially pronounced at Maro Reef, where recruitment declined

from 522.6 recruits m^{-2} yr^{-1} to 65.0 recruits m^{-2} yr^{-1} (Fig. 2a). Most islands/atolls in the NWHI experienced mass coral bleaching in 2004 (Kenyon and Brainard 2006), and responses to bleaching can include diminished reproductive capacity (e.g., Omori et al. 2001) and reduced recruitment (e.g., Obura 2001). However, *Pocillopora*, the major component of the recruits, was not heavily bleached at Maro Reef (Kenyon and Brainard 2006). The suite of causes behind this reduction in recruitment remains unclear.

The highest average annual recruitment rate was found at Maro Reef. The mesh of reticulate reefs adjacent to the lagoonal site where the plates were deployed may have facilitated retention of gametes and/or larvae compared to other NWHI locations where the neighboring reef structure was not as complex. Brown (2004) noted in the MHI that sites with higher recruitment rates were either in protected embayments or along coastlines with strong currents adjacent to reefs with high coral cover.

Remote Central Pacific Locations

The varying coral faunas and range of habitats in which the arrays were deployed at the five remote central Pacific locations preclude statistical comparison among locations. Each location is treated separately in the following discussion.

The arrays at Kingman Atoll were surrounded by a dense population of *Porites lutea* colonies. One hundred fifty-five coral and anemone species have been reported from Kingman Atoll (Brainard et al. 2005), but little is known of the timing of coral reproduction. Kenyon (2008) inferred that several episodes of spawning involving multiple *Acropora* species take place annually over 2 or 3 months beginning in late April at Kingman and Palmyra. Fresh settlement plates were deployed biennially before this inferred initiation of spawning and provided substrate for two annual periods of reproductive activity. Recruitment to the 2004–2006 cohort of plates was among the lowest rate documented in all remote central Pacific locations during the 6-year study (Fig. 3a), and the reasons behind this failure in recruitment are unclear.

The arrays at Palmyra Atoll were deployed in the lagoon, which experiences limited circulation and low coral abundance (J. Maragos, pers. comm.). One hundred sixty-eight coral and anemone species have been reported from Palmyra Atoll (Brainard et al. 2005), but little live coral is presently found in the lagoon. The consistently low recruitment rates (Fig. 3a) likely reflect the depauperate nature of coral communities in this portion of the lagoon.

The plates at Baker Island were deployed in a region of moderately high (~ 36%) coral cover dominated by *Acropora nobilis* (Coral Reef Ecosystem Division (CRED), unpubl. data). Eighty-eight coral and anemone species have been reported from Baker Island (Brainard et al. 2005) with assemblages dominated by *Montipora*, *Acropora*, *Pavona*, and *Pocillopora*, but no studies of coral reproduction have been conducted here. The average annual recruitment rate (6.4 ± 1.2 recruits m^2 yr^{-1}) was second only to that at Kingman Atoll.

The plates at Jarvis Island were deployed in a region of moderately high (~ 40%) coral cover dominated by *Montipora* and *Pocillopora* (CRED, unpubl. data). Forty-nine coral and anemone species have been reported at Jarvis Island (Brainard et al. 2005), with assemblages dominated by *Montipora*, *Pocillopora*, and *Pavona*, but no studies of coral reproduction have been conducted here. Recruitment rates were the highest from all remote central Pacific locations for the 2004–2006 cohort (Fig. 3a), but in the absence of data from more than one cohort, other generalizations cannot be made.

The arrays at Rose Atoll were deployed in the lagoon close to a patch reef with moderately high coral cover (~ 45%) dominated by *Favia*, *Montipora*, and *Astreopora* (CRED, unpubl. data). Observations of spawning by seven species (Itano and Buckley, 1988; Mundy and Green, 1999) off Tutuila, ~340 km distant from Rose Atoll, following the October or November full moon constitute the best available data by which to predict reproductive phenology of the 111 species of corals and anemones (J. Maragos, pers. comm.) at Rose Atoll.

All Locations

Average annual recruitment rates at all locations in the NWHI were higher than those at remote central Pacific locations, although adult coral cover is lower at all locations in the NWHI than any of the remote central Pacific locations (Kenyon et al. 2006, 2007a,b; CRED, unpubl. data). Hughes et al. (1999) also noted a lack of conformity between adult abundance and recruitment on the Great Barrier Reef. The range of substrata, depths, faunal diversity, submergence times, and metrics used to report recruitment in published scientific literature (Field et al. 2007) confounds comparisons with rates in the present study. With this caution, recruitment rates from studies in the MHI range from 0.2 recruits m^{-2} yr^{-1} (Polachek, 1978) to 1536 recruits m^{-2} yr^{-1} (Kolinski 2004). In a study of recruitment on the Great Barrier Reef at four hierarchical spatial scales, Hughes et al. (1999) determined that recruitment by broadcast-spawning corals was most variable at the largest spatial scale (sectors, each 250–500 km apart) and least variable among reefs within sectors, each 10–15 km apart. Future studies of recruitment in the NWHI, where the islands/atolls are separated by the scale of

sectors, could benefit from a similar hierarchical design, and future studies in all locations could benefit from spatial replication.

Acknowledgements

This study began with the idea by Russell Brainard for time series data on coral recruitment. The officers and crew of the NOAA Ships *Townsend Cromwell*, *Oscar Elton Sette*, and *Hi'ialakai* provided logistical support. Divers Michael Ellis, William Mowitt, Stephani Holzwarth, Joe Chojnacki, Brian Zgliczynski, Ronald Hoeke, Jamison Gove, Kevin Wong, Kyle Hogrefe, Chip Young, Elizabeth Keenan, Daniel Merritt, and Frank Mancini assisted with deployment of settlement plates. Matthew Dunlap conducted microscope analysis of the first two cohorts from the NWHI. Stephanie Schopmeyer entered data derived from microscopic analysis into a database. Permission to work in the NWHI was granted by the Pacific Remote Islands Wildlife Refuge Complex, U.S. Fish and Wildlife Service, Department of the Interior and the State of Hawaii Department of Land and Natural Resources. Permission to work at the remote central Pacific locations was granted by the Pacific Remote Islands Wildlife Refuge Complex, U.S. Fish and Wildlife Service, Department of the Interior. Funding from NOAA's Coral Reef Conservation Program supported this work.

INDIRECT EVIDENCES ON THE CONNECTIVITY OF CORAL REEFS OF THE GULF OF MEXICO AND THE MEXICAN CARIBBEAN

A. Chávez-Hidalgo*, G. De la Cruz-Agüero & E.A. Chávez

Centro Interdisciplinario de Ciencias Marinas. Instituto Politécnico Nacional. Av. IPN s/n

Abstract. Coral reef connectivity results from the export and import of species or reproductive product between localities. Possible exchange pathways between the reef ecosystems in the country are not known; such knowledge about coral reef connectivity could contribute to its management and conservation. The connectivity between reefs of the Gulf of Mexico and Mexican Caribbean was evaluated based on patterns of similarity. Information for 48 stony coral species in 19 localities was compiled from different sources. Species richness suggests that the highest coral biodiversity is located around Cozumel on the Caribbean with 33 species. Cluster analysis based on biological similarity between localities shows that the Veracruz Reef System (VRS) is more similar to the reefs of the Mexican Caribbean than those on the Campeche Bank. Correlation (Mantel test) of biological similarity with geographical distance, days of transport by currents and environment variables, was negative and highly significant, corroborating that biological similarity decreases with increasing distances. The hypothesiss that the reefs of the VRS and the Caribbean are more similar because these areas are less affected by hurricanes is proposed. This environmental stability would lead to an accumulation of Caribbean coral species that makes VRS more similar to the Caribbean than to those reefs in the Northern Veracruz or those in the Yucatan shelf.

Key words: Connectivity, Dispersion, Coral reefs, Similarity

Introduction

Coral reefs are open systems that exchange organisms, nutrients and reproductive products, wholly or partly mediated by water flow (Sale, 2004). The density of populations occupying the reef ecosystem depends in part on reproductive effort of the species in remote areas where gametes are released, on the eficiency of mechanisms of transport in terms of larval viability and level of connectivity, and on the own reproductive capacity and recruitment of local populations (Roberts 1997). Most coastal marine species have limited adult movement, so the relative short-lived pelagic larval stages represent the primary opportunity for dispersal. Following the pattern of surface currents, some attempts have been made to try and define the transportation routes that are followed by larval stages, resulting in the recognition of general pathways of connectivity amongst the different areas where coral ecosystems occur (Cowen et al. 2006).

Connectivity in the marine environment can also be constrained by biogeographic barriers as seen in terrestrial environments, which are not easy to discern, due to the short duration of larval stages and dispersal mechanisms by currents (Thorrold 2006). One way to infer connectivity from the ecological point of view, is to determine the similarity of ecosystems from background information such as species richness, number species shared, the similarity of environment and their relationship to geographical distance. In general, those communities that are farthest from each other should be the less similar due to their lower connectivity (Nenkola and White 1999; Steinitz et al. 2006). Such relationships between the reef ecosystems of the Gulf of Mexico and Mexican Caribbean is unknown, so better knowledge should contribute to improve decision-making in management and conservation.

Material and methods

Records of species of corals of the Gulf of Mexico and Mexican Caribbean (Fig. 1) were compiled from seven different sources with comparable methodology (Table 1). Data were organized in tables according to species abundance, dominance, and Shannon-Wiener diversity (Magurran 1988).

Depending on the parameters of the community, analysis of qualitative biological similarity was carried out first with data on presence/absence by applying the Jaccard and/or Sorensen indices (Nenkola and White 1999; Steinitz et al. 2006). Similarity was determined with the Manhattan distance as a measure of affinity and the method of Ward as a strategy of agglomeration.

Similarity was also explored using other indices (Legendre & Legendre, 1998). Correlation of biological similarity with the geographical distance, the days of transport by currents and environmental similarity was assessed using simple and partial Mantel test (Fortin and Gurevitch 1993). Geographical distances were estimated using a geographic information system (GIS), to construct the matrix of distances and the matrix of days of larvae drifting being transported by currents (mean annual velocity, Mariano et al., 1995). A matrix of environmental similarity was calculated using mean annual environmental factors (sea surface temperature, salinity, oxygen, nitrates, phosphates and silicates) obtained from the NOAA World Ocean Atlas 2005 (http://www.nodc.noaa.gov).

Results

Coral communities had the highest species richness (S) in Mahahual, with 37 species. The highest ecological diversity (Shannon-Wiener) was found in Cozumel, with 4.05 bits/ind. Exploration of presence/absence data did not allow us to find any clear pattern defining how biological similarity declines with increasing geographic distance; for this reason, the following analysis was performed using quantitative data of relative abundances of coral species.

Classification of sites allowed to identify a pattern of grouping the reef localities. Veracruz Reef System (VRS), in the southern Gulf of Mexico, shows higher similarity with localities in the Mexican Caribbean than with localities in the Northern Gulf of Mexico or with those on the Yucatan shelf (Fig. 2)

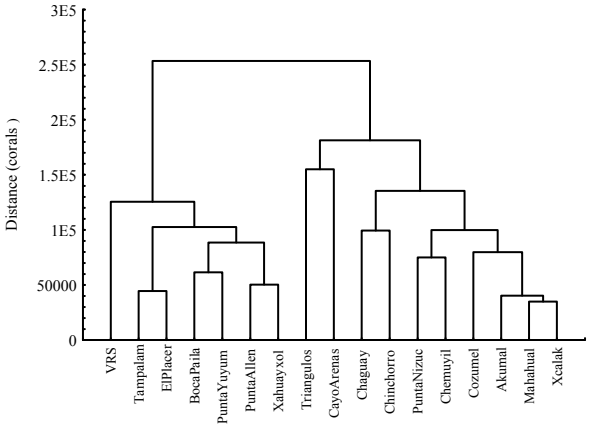

Figure 2. Cluster analysis (Manhattan distance, Ward method) for coral reef localities.

The first two Principal Components based on environmental variables explained 78.6 % of the total variance, with nitrates (0.98) and silicates (0.88) correlated positively with the first component. In the second component, the salinity showed positive correlation (0.89) whereareas sea surface temperature correlated negatively (-0.94).

The arrangement of localities in ordination space depicts a gradient of variability, with the reefs from the south and central Mexican Caribbean and the reefs from the Gulf of Mexico caracterized by low concentration of nitrates and silicates and relatively high concentration of phosphates (Fig. 3). According to the second principal component, the Mexican Caribbean localities were caracterized by warmer surface waters, but less salinity, while the Gulf of Mexico localities were more salty and waters with lower temperature (Fig. 3).

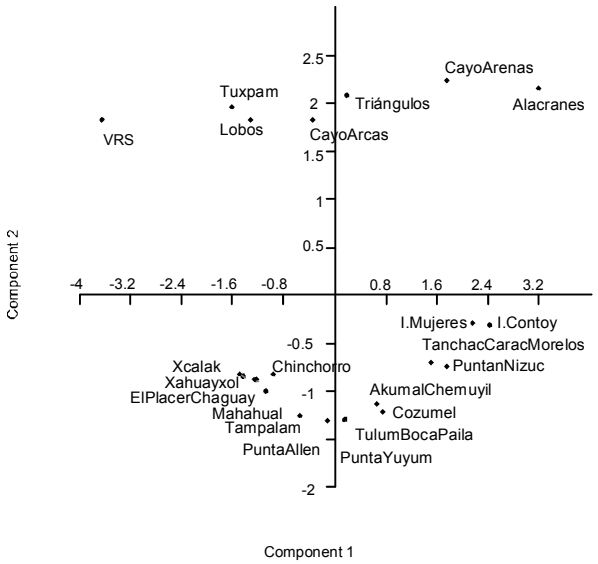

Figure 3. Principal Component analysis using components 1 and 2 as gradients of environmental variability (78.6% of total variance explained.)

A simple Mantel test was used to test the correlation of coral reef similarity with geographical distance, with the distance in days of transport as effect of current and with the environmental similarity showing negative correlations in all cases, except for biological similarity and days of transport by oceanic currents. In such statistical significant tests, the biological similarity between localities decreases as the geographical distance between them increases (Table 2).

Table 2. Simple Mantel test correlation between similarity and relevant distances matrices for coral reef localities. Correlation *r* and statistical significance (*p*) after 10,000 randomizations.

Simple Mantel test	*R*	*p*
biological similarity vs. distance (km)	-0.514	0.018*
biological similarity vs. days of transport	-0.384	0.076
biological similarity vs. environmental factors	-0.615	0.003*
distance (km) vs. days of transport	0.962	0.001*
environmental factors vs. distance (km)	0.885	0.001*
environmental factors vs. days of transport	0.751	0.001*

(*) statistical significance p<0.05

Prior to the partial Mantel test, the simple correlations between the matrices of the independent variables were obtained. All the combinations between them were positive, higher than 0.75 and highly significant (Table 1).

Table 3. Partial Mantel test for relevant matrix combination (vs.) with fixing effects from the third matrix (and) for coral reef localities. Correlation *r* and statistical significance (*p*) after 10,000 randomizations.

Partial Mantel test	*r*	*p*
biological similarity vs. distance (km) and days of transport	-0.572	0.003 *e*
biological similarity vs. days of transport and distance (km)	0.469	0.006 *e*
biological similarity vs. distance (km) and environmental factors	0.084	0.324 *e*
biological similarity vs. environmental factors and distance (km)	-0.402	0.019*
biological similarity vs. days of transport and environmental factors	0.150	0.219 *e*
biological similarity vs. environmental factors and days of transport	-0.537	0.008*

(*e*) spurious correlations, sensu Cramer (2003); (*) statistical significance p<0.05

A partial Mantel test indicated that the correlation of biological similarity with environmental factors, controlling the geographical distance and controlling for distance in days of transport, was negative and significant in both cases (Table 3). The other possible combinations were spurious according to Cramer (2003).

Discussion

Results obtained with the use of different techniques of classification and ordination enabled us to identify patterns of relationship between reef localities by their geographic range and to find results matching our working hypothesis, namely that closer localities are more similar to each other because they share a higher number of species rather than remote locations.

Cluster analysis showed an unexpected similarity between the Veracruz Reef System (VRS) with some more geographical distant reefs of the Mexican Caribbean. This is contrary to the expected idea that the VRS should be more similar to coral reef localities such as those in the Yucatan shelf or those in Northern Veracruz like Tuxpam or Lobos reefs, which are closer. One of the obvious reasons for this similarity is the number of shared species: of the 16 species of stony corals in the VRS, 14 of them are common or shared with Akumal and Mahahual in the Mexican Caribbean, while Cayo Arenas and Triangulos in the Yucatan platform, share only eight and five species with the VRS, respectively.

Higher similarity with the VRS, as well as the higher diversity of coral species at the regional level in the Mexican Caribbean, may indicate in the first case a historical accumulation of species richness in the context of higher stability associated with lower frequency of hurricanes in the Southwest Gulf of Mexico, whereas in the latter case, the recurrent impact of hurricanes in the Caribbean has caused a series of events of destruction and variable pulses of recruitment over time that have produced a diverse regional fauna

but a relatively low richness and low similarity scenario at the local level.

In the last 157 years (National Hurricane Center, 2008), the hurricane frequency as well as the accumulated impacts (frequency weighted by their intensity according to Saffir-Simpson scale) shows differences between regions in the study area. In the Gulf of Mexico, 17 hurricanes of a total of 28, had impacted the coral reefs on the Yucatan shelf, most of them with H1 category. Coral reefs in Northern Veracruz (Tuxpam and Lobos Island) had been impacted by twelve hurricanes, mainly H1 hurricanes, whereas the VRS has received only two impacts by hurricanes. On the Mexican Caribbean, coral reefs have been impacted by a total of 48 hurricanes, with the highest frequency in its northern portion with 28 hurricanes.

In the case of the coral reefs of the Mexican Caribbean and despite the observed patterns of association, there is a high heterogeneity in species composition, indicating that fewer coral species are shared among the sites in that region.

Within each geographic region, similarity between localities decreases with geographical distance, which is generally accepted by the current theory. Our results provide some evidence of the main patterns of connectivity amongst the reefs examined, concluding that ocean currents are the main driving factors responsible of the patterns shown; details of how other factors interact with interconnections of species and reefs are still unknown.

Using Ichthyoplankton Distribution in Selecting Sites for an MPA Network in the Sulu Sea, Philippines

W. L. Campos[1], P. D. Beldia II[1], C. L. Villanoy[2] and P. M. Aliño[2]

Abstract. This investigation was conducted to provide data and information needed to establish an ecologically functional network of MPAs in the Sulu Sea Basin, by making use of data on fish larval (ontogenetic) distribution and composition, as well as dispersal modeling in identifying areas with potentially high recruitment (sink) and or areas with high potential as egg and larval sources. During the transition to the NE Monsoon (October), highest egg concentrations were observed in the immediate vicinity of the atolls and reefs along Cagayan Ridge and in embayments along the western border of Sulu Sea (east coast of Palawan), but larvae were most abundant along a north-south mid-basin transect from Cuyo Shelf. to Cagayan Ridge. Large-scale circulation shows that the Cuyo Group of Islands to be a major source of larvae to the western half of Sulu Sea, while the prevailing strong northeasterly current isolates Cagayan Ridge from Western Sulu Sea. The ontogenetic distributions of larval groups are consistent with the above scenario. The results are discussed in the context of connectivities within Sulu Sea and their implications to fisheries management.

Key Words: ichthyoplankton, connectivity, Sulu Sea

Introduction

Most shallow water fish species produce pelagic eggs and larvae (Bone et al. 1995). As such, these early life stages may be carried by ocean currents away from where they were spawned (dispersal) and or retained by local circulation (e.g., entrainment cells) within the vicinity of spawning grounds. The extent of dispersal/retention ultimately determines how important source-sink connectivity (Roberts and Polunin 1991; Ratikin and Kramer 1996) is to recruitment and in what spatial scales this is relevant. Making this a major consideration in establishing ecologically functional networks of marine protected areas enhances success of management efforts in the long run. In this context, examining the distribution of ichthyoplankton (fish eggs and larvae) and relating this to potential dispersal or transport of planktonic larvae as influenced by circulation patterns are of critical importance.

The Sulu Sea is a deep semi-enclosed basin whose connections with neighboring basins is limited to passes with very shallow sills (Menez et al. 2006), which also serve as important "marine corridors" for larval exchange. This study characterizes the distribution of fish eggs and larvae in Central Sulu Sea in relation to basin-scale circulation during the transition to the Northeast monsoon season.

Materials and Methods

The ichthyoplankton survey was conducted in October 2006 and covered the area of Central Sulu Sea from Panay and Negros Islands along the eastern border westwards to the eastern coast of Palawan (Fig. 1). Transects were strategically located to allow sampling across simulated current flow patterns (Villanoy et al. 2007) typical for this time of the year, the transition to the NE monsoon which is a major spawning season for many tropical marine organisms in the Philippines.

Stations were laid out approximately every 10-15nm along each transect. Samples were collected by means of 15 minute horizontal (sub-surface; within upper 1m) and double oblique tows (maximum targeted depth of 100m) using a 335 µm conical plankton net attached to a 60cm diameter ring. Mechanical flowmeters were mounted across the mouth of the net to measure the volume of water filtered. Horizontal tows were intended to sample fish eggs which are normally buoyant and inactive, and are thus generally found close to the surface. Double oblique tows, on the other hand, were used primarily to reduce the effect of time of day on the samples. Fish larvae and other plankton exhibit vertical movement in the water column in relation to light, affecting their vulnerability to plankton nets during the daytime. By employing a combination of tows, comparisons of estimates of egg and larval

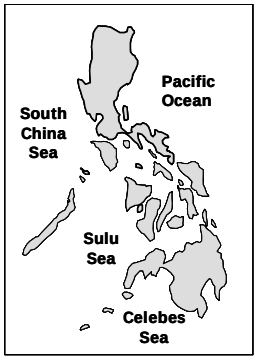

Figure 1. Map of the Philippines showing Sulu Sea (left) and the locations of stations surveyed in October 2006 (below). Note: arrows indicate the direction and relative magnitude of prevailing currents in the Sulu Sea in October (Villanoy et al., 2007)

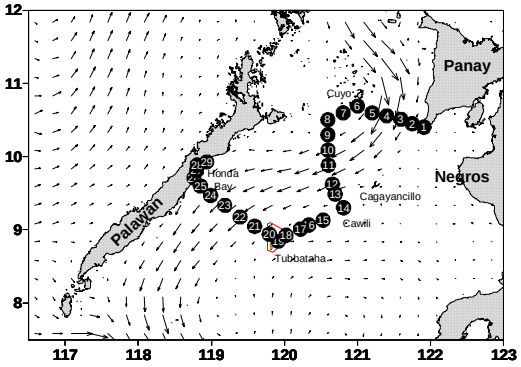

concentrations at different times of the day can be made.

Samples were fixed in 10% buffered seawater-formalin solution in the field and brought back to the laboratory for sorting, identification and stage (developmental) determination.

Results & Discussion

Plankton Abundance and Distribution

The distributions of fish eggs and larvae are shown in Figures 2a and b. Across all 29 stations, mean larval density was 113.6 ind/100m^3, which is around 5 times the overall mean larval density recorded for the same general area in April 2006 (mean = 18.0 ind./100m3; sd 20.3; Campos et al., 2007). Moderate to high larval concentrations were recorded in the three transects traversing the main current flow, with highest densities (mean = 189.6 ind./100m^3; sd = 32.5) observed between Cuyo Shelf and Cawili Is.. Moderate larval densities were observed along the transect from the southern tip of Panay Is. west to Cuyo Shelf (mean = 123.1 ind./100m^3; sd = 52.0) and from mainland Palawan east to Tubbataha (mean = 103.0 ind./100m^3; sd = 55.8), respectively. The lowest densities (mean = 33.5 ind/100m^3; sd = 25.1) were recorded along the transect from Cawili Is. to Tubbataha (Fig. 2a).

Mean egg densities in October (mean = 2.1 eggs/m^3; sd = 4.9) were also higher by an order of magnitude than observed concentrations in April 2006 (mean = 0.29 eggs/m^3; sd = 0.45; Campos et al. 2007), although variability in both surveys was high. High variability is generally due to the patchy distribution of fish eggs. During the survey, high egg concentrations were recorded off the tip of Panay, in the Cuyo group of islands, Cawili Is., Tubbataha atoll, and Honda Bay in Palawan (Fig. 2b). Mean densities in these locations showed a mean of 5.7 eggs/m^3 (sd = 7.3), which is about 30 times the average densities in the rest of the other stations (mean = 0.2 eggs/m^3; sd = 0.12).

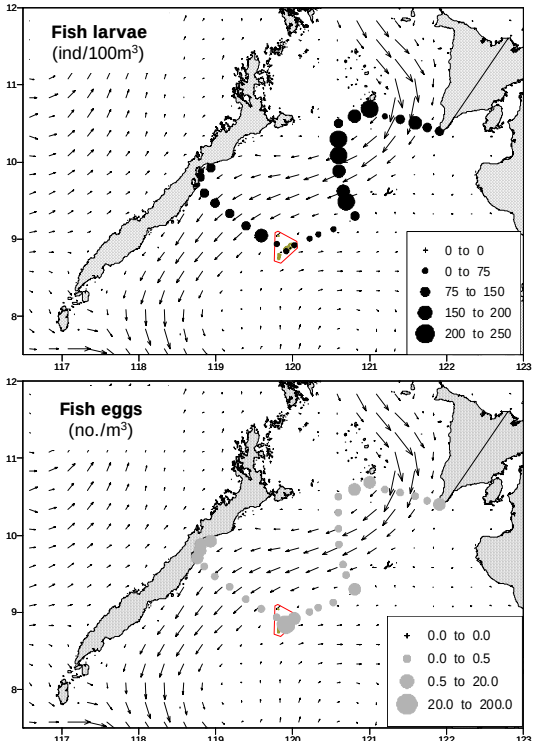

Figure 2. The density distribution of fish larvae (upper) and eggs (lower) in the Central Sulu Sea in October 2006.

Larval Assemblage Structure

A cluster analysis was performed on larval composition data from the 29 stations and the results are summarized in Fig. 3 and Table 1. Three major station clusters were formed by the analysis: Palawan Coast, Cagayan Ridge (Tubbataha to Cawili), and stations within the main flow. The latter group was further subdivided into a sub-group along the eastern margin of the main flow, and another within the main axis. The relative composition of larval assemblages in these clusters is shown in Table 1. The cluster of shallow stations along the coast of Palawan is dominated by larvae of soft-bottom demersal fish,

such as gobiids, nemipterids and cynoglossids. On

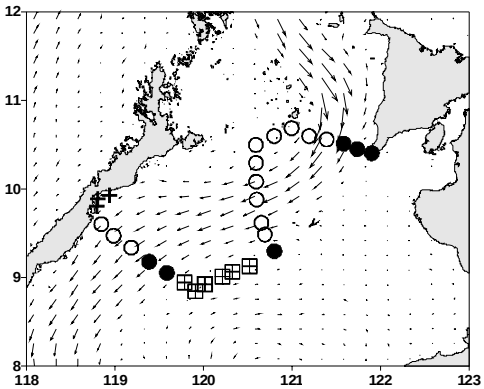

Figure 3. Location of station clusters in the Central Sulu Sea in October 2006: Palawan coast (+), Cagayan Ridge (⌗), Main flow (○), and main flow margin (●).

the other hand, the Cagayan Ridge cluster of deep

Table 1. Relative abundance (%) of the various larval groups in the four station clusters.

Larval groups	Palawan Coast	Cagayan Ridge	Main Flow Margin	Main Flow
Demersal	67.0	12.1	11.1	21.3
Mesopelagic	3.8	44.8	57.0	22.7
Reef-associated	23.5	23.2	17.0	41.0
Epipelagic	1.3	5.3	8.7	8.7
Unidentified	4.3	14.5	6.2	6.3
	100	100	100	100

open water stations was dominated by larvae of mesopelagic fish, such as myctophids, gonostomatids and paralepidids, but showed substantial contributions (23.2%) from reef-associated groups like scorpaenids and balistids. Reef-associated larvae in this cluster likely originate from the atolls or islands along the Ridge. The stations of the main current flow showed assemblages comprised primarily of reef-associated and mesopelagic fish larvae. These stations are in deep open water and this explains the abundance of mesoplegaic fish larvae which are likely spawned in open water. However, because reef fish generally spawn in reef areas, their abundance in this cluster indicates their origin from sources upstream of the main current flow, like Cuyo Shelf, where extensive shallow reef areas are located. Among stations in this cluster, the ones along the eastern margin of the main flow show much larger contributions from mesopelagic fish larvae (57%) than stations within the main axis of the flow (22.7%).

Ontogenetic Distribution

The ontogenetic distribution of reef-associated larvae show a progression from higher upstream concentrations in younger (preflexion) stages to higher downstream concentrations in older (postflexion) stages (Figs. 4a-c). A similar pattern was shown by larvae of demersal fish. These results are consistent with spawning in Cuyo Shelf and subsequent transport towards the southwest in the direction of the main flow as larvae age and develop. In contrast, mesopelagic larvae do not show any progression of concentrations with age (Figs. 5a-b). This may be attributed to more open and deep water

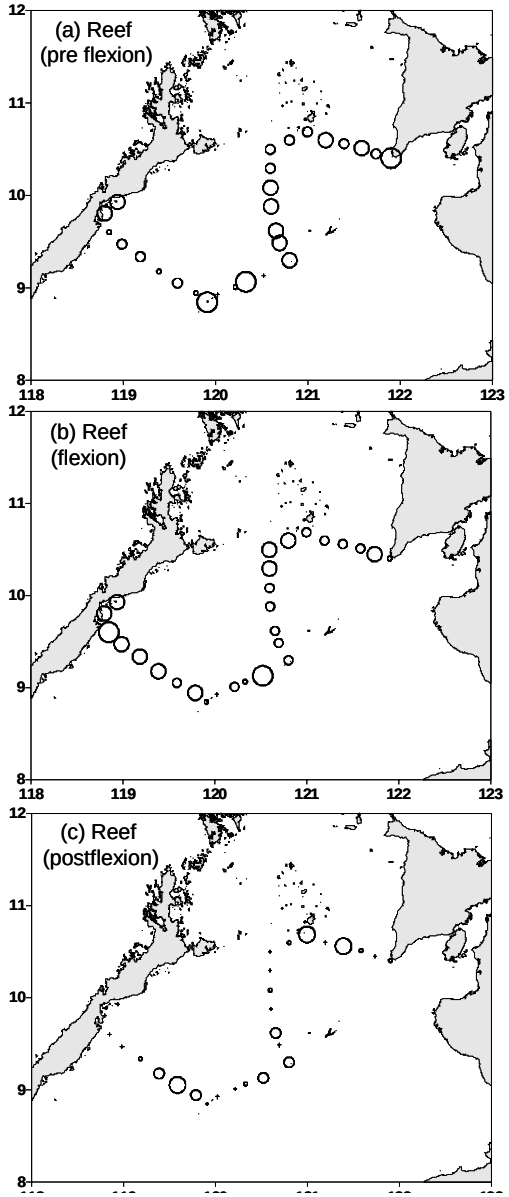

Figure 4. Ontogenetic distribution of larvae of reef-associated fish in the Central Sulu Sea in October 2006.

spawning grounds of these fish, which covers most of the Sulu Sea. No examination of epipelagic larvae was done due to their low number in the samples.

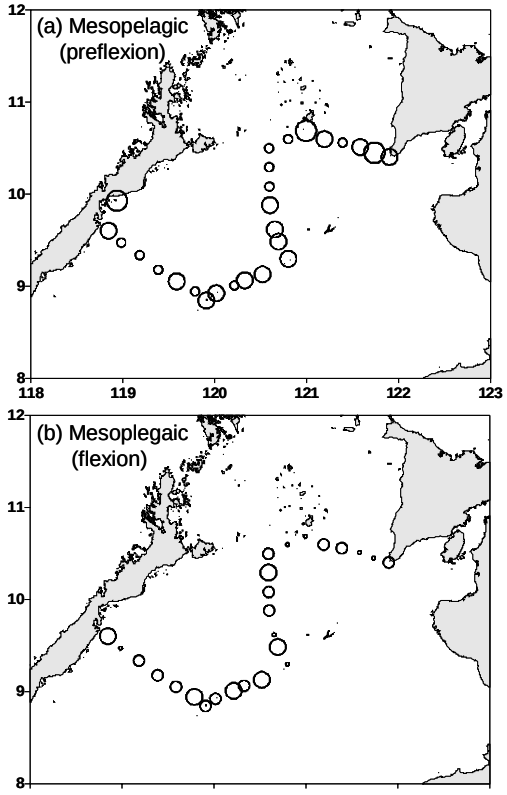

Figure 5. Ontogenetic distribution of larvae of mesopelagic fish in the Central Sulu Sea in October 2006.

Larval distribution patterns and hydrography

Large scale circulation in the Sulu Sea in October is dominated by a strong current flowing from the northeast and then southwards along the coast of Palawan (Fig. 1). This current covers a wide path, extending from Cuyo Shelf all the way to Panay, and from the east coast of Palawan to just west of Cawili Island. Because of the relatively strong current in the main axis, it is unlikely that plankton are able to cross it. This effectively isolates the atolls and islands of Cagayan Ridge from western Sulu Sea, at least during this time of the year. However, entrainment further upstream may result in downstream dispersion within the flow.

A review of egg and larval distributions in relation to large-scale water movement allows scenario-building. The patchy larval concentrations along the transect from Cuyo to Panay (Fig. 2a) would be consistent with spawning at the endpoints of this transect, as also shown by egg concentrations at these locations (Fig. 2b), and not further north. If major spawning had taken place further north of Cuyo Shelf, entrainment in the strong southward current would have caused larval concentrations along this entire transect to be more homogeneous. On the other hand, major spawning in the Cuyo group of islands would still be delimited by the south-flowing current in the area near Panay, but entrainment would result in high and relatively homogeneous larval concentrations in transects further downstream (i.e., Cuyo to Cawili), as was observed during the survey (Fig. 2a). The preponderance (> 70%) of shallow water fish larvae (e.g., demersal, epipelagic and reef-associated) within the main flow (Table 1) is consistent with Cuyo Shelf being the major source. The reduced larval concentrations between Tubbataha and mainland Palawan may be due to larval settlement (recruitment) along the stretch of Palawan's coastline north of Honda Bay.

The difference in assemblage composition between the cluster of stations along the eastern margin of the main flow and those within the main axis of the flow is consistent with Cagayan Ridge being isolated from Western Sulu Sea during this time of the year. Spawning grounds along the Ridge, as indicated by egg concentrations (Fig 2b), will likely be self-feeding, at least during this season, with apparent transport being facilitated by a weak gyre formed by currents immediately west of the Ridge flowing towards the southwest and those immediately east flowing towards the opposite direction. Again, the similarity in taxonomic make-up of assemblages in the main flow margin and the Ridge (i.e. > 44% mesopelagics; moderate amounts of reef-associated larvae; Table 1) is consistent with this scenario.

Implications for fisheries management

For the Central Sulu Sea, the extensive Cuyo Shelf area appears to be a major source of larvae for habitats along the East Coast of Palawan, and perhaps even further south, at least during the transition to the NE monsoon. Improving protective management efforts in Cuyo Shelf would benefit an extensive area downstream. Also during this season, spawning and recruitment within Cagayan Ridge seem to be limited locally. Hence, management efforts here would have little impact on fishing to the west, although the situation will likely be different in other seasons. What happens during the rest of the year is still largely unknown but on-going analyses of survey data from the Summer (April) 2007 will provide more information on this.

While it is believed that dispersal from MPAs with increased spawning biomass is the mechanism that enhances sustainability of fishing downstream,

unequivocal empirical evidence for this is still largely unavailable (Russ 2002). The results of this study do not provide such data, but they indicate which portions of the Central Sulu Sea are functionally connected during the transition season to the NE monsoon, and where improved management can be focused.

There are currently over a thousand marine protected areas in the Philippines, with more than 1/3 covering less than 10 ha. Recent figures show that only about 10% of these are properly managed (Campos and Alino 2008), due primarily to scarce support resources that are also spread out thinly. Under such circumstances, information provided from this study provides a strategic framework for optimizing management efforts with enhanced prospects for long term success.

Abstract. Genetic structure was studied in the coral *Pocillopora damicornis* in three areas of coral development of the Mexican Pacific (MP). Specimens were collected from six localities: El Portugues and Punta Gaviotas located inside the Gulf of California (GC), Punta Arenas and Isla Redonda from the entrance of GC, and Las Dos Hermanas and La Entrega in the south of the MP. Exclusive genotypes were observed in the northern and southern populations. Genetic variation was similar along the MP, although slight higher variation was observed in the southern populations. Most of the populations presented significant deficits heterozygotes. These deficiencies could be due to the predominance of the asexual reproduction by fragmentation, localized sexual reproduction, inbreeding and/or Wahlund effect among localities, and different mortality events by natural disturbances. Cluster analysis based on genetic distance showed three groups by geographical proximity: two populations inside the GC, those ones located in the entrance of the GC, and two populations located at the south of the MP. Mean significant F_{ST} value (F_{ST} = 0.153) indicated a genetic structure. Differences in sexual and asexual reproduction among the localities coupled with local recruitment and currents patterns are possibly generating the genetic structure observed in the populations of *P. damicornis* in the MP.

Key words: Population structure, *Pocillopora damicornis*, Mexican Pacific, population genetics.

Introduction

The coral *Pocillopora damicornis* is one of the dominant coral species in reef systems of the eastern Pacific. This coral is distributed from the Gulf of California in Mexico to Ecuador, including all the nearby oceanic islands (Glynn and Ault 2000; Pérez-Vivar et al. 2006). This species is one of the most studied and widely distributed reef corals in the world. Examination by allozyme electrophoresis of this species has allowed determinate the genetic structure in coral populations throughout the Indo Pacific (Stoddart 1984; Ayre *et al*. 1997; Yu *et al*. 1999; Ayre and Hughes 2004; Smith-Keune and van Oppen 2006).

In the Mexican Pacific (MP), reproductive studies indicated that this species can reproduce both sexually (spawn gametes) and asexually (fragmentation) and presents a geographic variation in its reproductive mode along the Mexican Pacific (Chávez-Romo and Reyes-Bonilla 2007; Carpizo-Ituarte *et al*. 2009). In addition, there is not information about the genetic variation of *P. damicornis* in the MP. Genetic studies realized in other coral species as *Porites panamensis* (Paz-García *et al*. 2009b) and *Pavona gigantea* (Saavedra-Sotelo 2007) have showed a genetic structure in their populations.

Our aim was to determine the genetic structure of the coral *P. damicornis* along of the Mexican Pacific. This study is relevant due the populations are in active recovery after bleaching and mortality caused by the 1997-98 El Niño event (Carriquiry *et al*. 2001; Reyes-Bonilla 2001).

Material and Methods

Sample Collection. We collected 22 to 48 fragments (2 m of depth) of *P. damicornis* from six localities along of the MP (Fig. 1): El Portugues (POR) and Punta Gaviotas (PGA) inside of the GC (GC); Punta Arena de la Ventana (PAV) and La Isla Redonda (IRD) in the entrance of the GC; and two localities from the south of MP, Las Dos Hermanas (LDH) and La Entrega (LET). The coral fragments were frozen in

liquid nitrogen and transported to the laboratory, where they were stored at -80°C.

Figure 1. Collection areas. Points indicate collected sites along the Mexican Pacific. **POR** El Portugues, **PGA** Punta Gaviotas, **PAV** Punta Arenas, **IRD** Isla Redonda, **LDH** Las Dos Hermanas and **LET** La Entrega.

Electrophoresis. We conducted a coral tissue extraction in Stoddard's buffer modification (Stoddart 1983, Weil 1992) using a sonic desmembrator. Homogenates were centrifuged at 2600 g for 10 min at 4 °C, and the supernatants were stored at -80 °C. We determinate the concentration of total proteins from each sample by Bradford's method (Bradford 1976) and 25 to 50 µg of sample was used for the analysis of each enzyme system (Paz-García et al. 2009a). Allozyme analysis was carried out using vertical electrophoresis with 8%T polyacrilamide gels (Manchenko 1994). Four enzyme systems were used: Leucyl glycyne glycyne peptidase (LGG 1, E.C. 3.4.11.1) enzyme malic (ME 1&2, E.C. 1.1.1.40), glutamate dehydrogenase (GDH 1, E.C. 1.4.1.3) and esterase (EST 1&2, EC 3.1.1.1). Tris-Glycyne Buffer was used in the electrophoresis. Alleles were assigned a value based on the ratio of their electrophoretic mobility relative to that of the most common allele.

Statistical analyses. Genetic variability was calculated for each population and the Hardy-Weinberg equilibrium (HWE) was tested by χ^2 analyses, using the Biosys-1 and GENPOP programs (Swofford and Selander 1981; Raymond and Rousset 1995). The magnitude and direction of departures from HWE at each locus were also assessed to each population. These departures were expressed as Wright's fixation index (*f*), where positive and negative values represented deficits and excesses of heterozygotes, respectively (Wright 1978). Unbiased genetic distance was used for cluster analysis, calculated in TFPGA software (Nei 1978; Miller 1997). Wright's *F* statistics were calculated to determine the degree of differentiation among populations (Weir and Cockerham 1984). We calculated pairwise F_{ST} estimates between each pair of populations. F_{ST} were tested for difference from zero permuting (10 000 replicates) alleles between samples with exact G-test (Goudet *et al*. 1996), as implemented in FSTAT v. 2.8 (Goudet 1995). We applied a sequential Bonferroni correction to reduce the chance of type I errors (Rice 1989).

Results

Six loci were scored from four enzyme systems, one monomorphic and five polymorphic. Exclusive genotypes were observed in the northern (POR: LGG-1^{AB}; PGA: LGG-1^{AB} and LGG-1^{BC}) and southern (LDH: LGG-$1^{AC,}$ LGG-1^{BC} and LGG-1^{CD}; LET: LGG-1^{AC} and LGG-1^{CD}) populations (Anexus I). Allelic diversity was 2.3 in the populations from inside and entrance Gulf of California and 2.5 in south of MP (Fig. 1a). Genetic variation was slight higher in southern populations (LDH and LET). All populations presented significant deviations of Hardy-Weinberg equilibrium in deficits of heterozygotes (Fig. 1b and Table 1).

The UPGMA cluster analysis, based on Nei's (1978) unbiased genetic distance, showed three groups by proximity geographical: I) the populations from inside of the GC, II) two populations from the entrance of the gulf and III) the populations of the south of MP as other cluster (Fig. 2). The individual inbreeding coefficient (F_{IS}) and the total inbreeding coefficient (F_{IT}) were significantly different from zero in each locus and mean value (Table 2). F_{ST} values were statistically significant, except for locus EST-2, and ranged from 0.062 to 0.213. Mean significant F_{ST} value (F_{ST}=0.153) indicate a population structure of *P. damicornis* in the MP (Table 2).

F_{ST} values calculated between pairs of populations, ranged from 0.027 to 0.420 (Table 3). These comparisons showed a great genetic subdivision of the populations from LDH and LET with the other analyzed populations (Table 3).

Discussion

Allelic diversity in most populations of *Pocillopora damicornis* from the Mexican Pacific showed slight lower values (2.2-2.5; Fig. 2a), compared with those reported in six populations from Japan which ranged of 3.1 to 3.8 and six habitats from One Tree Island Reef, Australia with values from 3.5 alleles per locus (Adjeroud and Tsuchiya 1999; Sherman et al. 2005). In addition, a declination of allelic diversity with increasing latitude (from 3.6 to 1.3) was observed in *P. damicornis* along the east of mainland Australia. This variation suggests a high genetic differentiation among the populations (Miller and Ayre 2008). Therefore, the observed values of allelic diversity suggest a lower genetic differentiation among the populations from the PM.

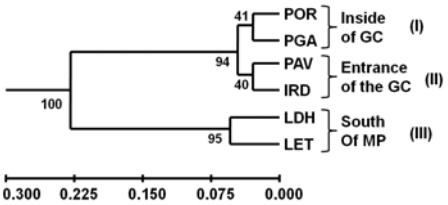

Figure 3. Cluster analysis based on Nei's (1978) unbiased genetic distances showing relationship among populations of *Pocillopora damicornis* from the Mexican Pacific. Bootstrapped values over 40% (based on 1000 randomizations) are shown next to corresponding nodes.

The slight higher genetic variation and exclusive genotypes found in the southern populations of *P. damicornis*, could be due to a larval dispersion coming from the populations from Central America (Panama, Costa Rica and Galapagos Islands). Possibly originated by a high genetic diversity in those populations that perhaps have a past genetic contribution of the populations from the Indo Pacific. In addition, recent studies realized in Panama, Clipperton Island and Hawaii, indicate that trans-Pacific gene flow in *P. damicornis* between the Central and Eastern Pacific is restricted; and the Eastern Pacific corals exist in relative isolation from their Central Pacific counterparts and interact with each other differently (Combosch *et al*. 2008).

The observed heterozygosis values ranged from 0.127 to 0.378 (Fig. 2b) and they are similar to six populations from Japan that present an asexual reproduction as main mode in the maintenance of their populations (ranged from 0.244 to 0.366; Adjeroud and Tsuchiya 1999). We detected significant deviations from HWE in each population (Table 1). Significant heterozygous deficit has been commonly observed in coral species (Adjeroud and Tsuchiya 1999; Nishikawa and Sakai 2005; Miller and Ayre 2008; Paz-García et al. 2009). These deviations has been associated to the predominance of the asexual reproduction by fragmentation, inbreeding and/or Wanhlund effect among localities, as consequence of different events of recruitment of different cohorts and for different coralline communities, and different mortality events by natural disturbances (Ayre et al. 1997; Adjeroud and

Tsuchiya 1999; Sherman et al. 2005; Ayre and Hughes 2004; Constantini et al. 2007).

Cluster analysis based on Nei's (1978) unbiased genetic distance suggests that the populations of *P. damicornis* that are from inside the GC (POR and PGA), and the entrance (PAV and IRD) of the GC, possess slight genetic differences (Fig. 3). While the LDH and LET present high genetic differences with northern populations. This pattern suggests a subdivision among the populations of *P. damicornis* and coincides with the observed in *Porites panamensis* along the MP (Paz-García *et al*. 2009b). These results suggests that populations from inside and the entrance of GC may be a group genetically more homogeneous, while that southern populations showed a genetic differentiation that could be due to the high frequency of natural phenomenon that they are generally presented along the MP (e.g. hurricanes, torments, ENSO events, upwelling areas; Medina-Rosas *et al*. 2005; Paz-García *et al*. 2009b). Furthermore the values of the bootstrapped in the cluster analysis corroborate this differentiation in the most southern populations (Fig. 3) and it coincides with that found in other coral species studied in the MP as *P. panamensis* and *P. gigantea* (Saavedra-Sotelo 2007; Paz-García *et al*. 2009b).

Significant differences found in the individual inbreeding coefficient (F_{IS}) and the total (F_{IT}) of the populations (Table 2), indicate a heterozygote deficiency and a possible local recruitment in the populations of *P. damicornis* in the PM. F_{ST} values in the most loci and mean significant F_{ST} value (F_{ST} = 0.153) indicated a high genetic structure in the populations of *P. damicornis* in comparison with other coral species studied in the MP as *P. panamensis* (F_{ST}=0.104; Paz-García et al. 2009b) and *P. gigantea* (Φ_{ST} 0.10-0.20; Saavedra-Sotelo 2007). Previous studies in the GC and MP have found population subdivision in different marine invertebrates and fishes groups (De la Rosa-Vélez et al. 2000; Riginos y Nachman 2001; Valles-Jimenez et al. 2005; Paz-García *et al*. 2009b). Different factors can generate a population genetic subdivision in the MP, as biogeography, distance geographic, habitat discontinuities, temperature gradients and upwelling areas (De la Rosa-Vélez et al. 2000; Riginos and Nachman 2001; Halfar et al. 2005; Valles-Jimenez et al. 2005).

In addition, the genetic differentiation observed in populations of *P. damicornis* could be due to differences in sexual (spawning gametes) and asexual (fragmentation) reproduction among the localities of the MP (Chávez-Romo and Reyes-Bonilla 2007; Carpizo-Ituarte *et al*. 2009). Studies realized in Japan and Australia have been reported differences in the reproductive strategies of *P. damicornis* and the main reference that the asexual reproduction contributes substantially in the genetic structuring and in the maintenance of established population of the species (Stoddart 1984a, b; Adjeroud and Tsuchiya 1999). Fragmentation has been observed as common reproductive strategy in the populations of the *P. damicornis* in the MP. Patches of this species easily colonize soft substrates (sand or gravel) after their branches become detached following cyclones; these branches attach themselves to the bottom and continue developing (Reyes-Bonilla 2003). However, recent studies show that the population of PGA present evidences of sexual reproduction (Chávez-Romo and Reyes-Bonilla 2007), which would explain because the populations of inside the GC have a close genetic relationship with the populations the entrance of the GC. Although previous studies mention that the population from IRD presents an asexual reproduction for fragmentation way (Carpizo-Ituarte *et al*. 2009).

Nevertheless, although the reproduction influences in the genetic differentiation, it is not considered to be the only factor. The local recruitment coupled with currents patterns may limit the larval dispersion and generate the genetic structure observed in the populations of *P. damicornis* in the MP. The possibility has been mentioned that the Coastal Current Costa Rica (CCCR), in direction south to north, transports coralline propagules from Central America until Oaxaca, for the likeness of coralline species among these areas (Glynn and Wellington 1983; Reyes-Bonilla and López-Pérez 1998). Also, dispersion may occur from Oaxaca to Bahia de Banderas and from there to the Gulf of California. However the exclusive genotypes found in the OAX populations (LDH: LGG-$1^{AC,}$ LGG-1^{BC} and LGG-1^{CD}; LET: LGG-1^{AC} and LGG-1^{CD}) indicate that not all the coral species can be dispersed in the same way because different oceanic fronts exist to the south of Bahia de Banderas and the Gulf of California and that which coincides with that observed for *P. panamensis* along the MP (Reyes-Bonilla 2003; Paz-García *et al*. 2009b). Also, recent studies of the reproductive biology of *P. damicornis* in the population LET showed evidences that these reproduce in an asexual way (fragmentation; Carpizo-Ituarte *et al*. 2009), that which would support the fact that the genotypes found in LDH and LET were exclusive of these populations due a dispersion capacity doesn't exist toward the north. The dispersion could be limited between coral population with sexual reproduction by the existence of long sand barriers and mangroves communities localized along the MP (Glynn y Ault 2000; Reyes-Bonilla 2003). However, it is necessary to carry out other studies that analyze the ecology, reproduction and genetics of the populations of *P. damicornis* to

understand the relationship that exists among these ecosystems along Mexican Pacific.

Abstract. Whether south west Indian Ocean reef coral communities are resilient to anthropogenic and natural stressors will depend on their inherent ability to adapt to change. In this study, reef coral population diversity and relatedness were investigated at varied scales using molecular methods. Genetic diversity may be used as a proxy to gauge both the population dynamics and resilience of a community and was thus measured in two corals with different reproductive modes, larval dispersal capabilities and life history strategies. We used an intron region in the nuclear DNA of *Acropora austera* and the ITS region of the ribosomal DNA of *Platygyra daedalea* to compare genetic variability between populations. In *A. austera* there appears to be regular genetic exchange between populations in the region. The ITS region has, however, been demonstrated to yield inconclusive results. Local oceanography dictates that northern reef systems may be considered the source populations of those in the south. However, local reef-coral genetic diversity and connectivity may be better judged with a combination of finer resolution molecular markers.

Key words: Indian Ocean, reef-coral, genetic diversity, connectivity.

Introduction

Many scleractinian corals produce propagules which may move between habitats suitable for recruitment in a mobile pelagic stage which has potential for long-distance dispersal. Consequently, initial hypotheses considering larval viability proposed large genetically-unstructured populations for these marine invertebrates (Avise 1998). However, measuring gene flow as a proxy for movement using allozyme studies has confirmed that although some populations of hard coral showed high levels of gene flow, they also had structured populations (Ayre and Hughes 2004, Dai *et al.* 2000, Goffredo *et al.* 2004, Hellberg 1994, Nishikawa and Sakai 2005).

Various studies of genetic variability have revealed the relatedness of life strategy to connectedness of populations (Hellberg 1994; Bastidas *et al* 2002; Goffredo *et al*. 2004; Miller and Ayre 2004, LeGoff-Vitry *et al.* 2004), population structure (Mackenzie *et al.* 2004), speciation (Fukami *et al.* 2004, Marquez *et al.* 2002) and reticulation within species (Diekmann *et al.* 2001). Genetic information may reveal unexpected patterns of population structure and gene flow in hard reef corals and thus is a powerful tool in their management.

A recent review showed that little genetic work has been conducted on marine organisms in the south west Indian Ocean (SWIO) (Ridgway and Sampayo 2005). A number of studies have subsequently been published which shed light on patterns of connectivity and structure in scleractinia and their symbionts in the SWIO (Ridgway *et al.* 2008; Souter and Grahn 2007; Mangubhai and Souter 2007; Macdonald *et al.* 2008). Oceanic waters of Maputaland in the northern KwaZulu-Natal province of South Africa harbour the southern-most communities of coral in the SWIO (see Fig. 1). These communities comprise approximately 90 species of coral (hard and soft) which form the basis for these diverse communities (Schleyer 1999). Further north, the Bazeruto Archipelago also supports a diverse assemblage of corals on accretive reef systems. A gradient of species diversity decreasing from north to south (Obura 2000), along with predominantly southerly offshore currents in the Mozambican channel (5cm.s^{-1}, Lutjeharms 2006) implies that the more diverse northern reefs may be seeding the southern reef coral systems. This, however, has not been tested with appropriate genetic marker systems. As less than 2% of the coast is under any sort of management (Wells and Ngusaru 2004), regional authorities are developing management plans for local exploited resources. We sampled the east African coastline from a number of sites between northern Maputaland, South Africa and southern Tanzania. We collected *Acropora austera*, a widespread coral with a broadcast-spawning reproductive strategy common to the scleractinia (Carroll *et al*. 2006). We also sampled a Favid,

Platygyra daedalea, which, although also a broadcast spawner, displays a life strategy with slower growth and a pattern of intra-reef dispersal different from that observed in *A. austera* (Miller and Babcock 1997).

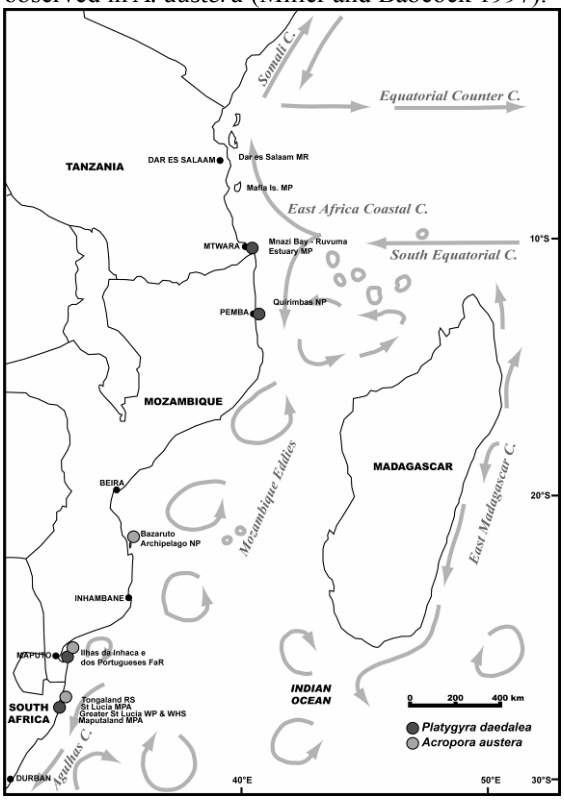

Figure 1. Currents, eddies and sampling locations of *A. austera* and *P. daedalea* in the SWIO study area.

*W*e used nuclear intron sequences similar to those developed by Concepcion *et al.* (2007) for *A. austera* specimens and ITS sequences for *P. daedalea*. ITS rDNA, however, is subject to concerted evolution, the rate of which may either obscure (Vollmer and Palumbi 2004) or resolve phylogenies (Lam and Morton 2003) and introgressive recombination (Vollmer and Palumbi 2004, Diekmann *et al.* 2001) which may further obscure inter-species variation and inter-population variation. This has, however, only been shown in certain families of the scleractinia (*Acroporidae*) (Vollmer and Palumbi 2004) whereas analysis of this region has revealed significant population differentiation in the *Faviidae* (Rodriguez-Lannetty and Hoegh-Guldberg 2002, Lam and Morton 2003), particularly within the genus *Platygyra*. We sequenced specimens from each collection locality using nuclear markers to obtain an initial estimate of nuclear genetic variability.

Materials and Methods

Corals were sampled from sites along the east African coast, using SCUBA and snorkel diving. Care was taken to avoid the collection of clone-mates by sampling colonies separated by at least 5m. Samples were immediately stored in either a dimethyl sulfoxide (DMSO) salt buffer or 70 % ethanol. All DNA was isolated using a Fermentas Life Sciences^{TM} genomic DNA purification kit as per their extraction protocol.

Acropora austera DNA was amplified using single-copy nuclear intron primers developed at the Centre for Marine Studies (CMS) at the University of Queensland (Ridgway, unpublished data). These amplify a hypervariable intron region of the carboxy-anhydrase gene. PCR reactions contained: 1µl sample template, 21.68µl dH_2O, 3µl 10X Platinum Taq PCR buffer mix, 0.9µl 50mM $MgCl_2$, 0.6µl 40mM dNTP mix, 0.84µl of each primer (10µM) and 0.12µl Platinum Taq 5u/µl (Invitrogen^{TM}) . The following thermal cycle was used for the PCR: [94°C for 2 minutes], 40 X [(94°C for 60 seconds), (51°C for 60s), (72°C for 2 m)], [72°C for 10m], [10°C∞]. Samples were sequenced on an ABI 3730 capillary sequencer at Inqaba Biotechnology^{TM}.

Platygyra daedalea DNA was amplified using the A18S and ITS4 primers developed by Takabayashi *et al.* (1998). PCRs contained: 1µl specimen DNA, 21.68µl dH_2O, 3µl 10X supertherm Taq PCR buffer mix, 1.8µl 25mM $MgCl_2$, 0.6µl 40mM dNTP mix, 0.84µl of each primer at 10µM concentration and 0.24µl supertherm Taq. The following thermal cycle was used for PCR amplification: [95°C for 10m], 40 X [(94°C for 45s), (51°C for 45s), (65°C for 1m)], [72°C for 10m], [10°C∞]. Sequencing showed that some specimens were polymorphic and that cloning the samples would be necessary in order to obtain good quality sequence data. Samples were cloned at Inqaba Biotechnology, Pretoria SA, and re-sequenced.

*A*ll sequences were aligned using Bioedit, a sequence alignment package (Hall 1999). Sequence variation was compared using Arlequin 3.11 (Excoffier *et al.* 2005) and DNAsp (Rozas *et al.* 2003). A minimum spanning network was constructed in Arlequin 3.11 (Excoffier *et al.* 2005) for *A. austera* haplotypes and drawn using MrEnt 2 (Zuccon and Zuccon 2008).

Results

*S*equencing - Samples were collected from throughout the study area (Fig. 1, Tab. 1). *A. austera* carbonic anhydrase intron DNA sequences were 155 base pairs (bp) long, had a GC composition of 43.5% and showed a total of 12 variable sites among all 51 sequences. These 51 sequences comprised 9 haplotypes, with haplotype diversity (hd) of 0.697 (std dev = 0.064), which were shared amongst the populations studied (Tab. 2). The complete ITS region (ITS1-5.8S-ITS2) was sequenced for 22 *P.*

daedalea samples. The total sequence length was 374 bp whilst the G+C content was 58.3 %. These 22 sequences comprised 15 haplotypes with hd = 0.939 (std. dev. = 0.029) and $\pi = 4.9$

Table 1. Number of specimens from each site along the east African coast analysed in this study.

Sampling location	*Acropora austera*	*Platygyra daedalea*
Two-mile reef	18	3
Nine-mile reef		2
Inhaca Island – Bareirra Vermelho	6	6
Inhaca Island – Baixo Danae	13

For *A. austera,* analysis of molecular variance (AMOVA) carried out in Arlequin 3.11 (Excoffier *et al* 2007) yielded $F_{ST} = 0.18$ ($p < 0.01$).
Barreira Vermelho (BV) was, however, found to show significant pairwise Fst values; when it was removed from the analyses the AMOVA showed no significant structure at any level. DNAsp was used to calculate the average number of migrants per generation ΔNm (Nei 1982) = 0.71 and the inter-populational gene diversity γst = 0.26. A minimum spanning network (MSN) was constructed to illustrate relationships between haplotypes and their distribution amongst populations (Fig. 2).

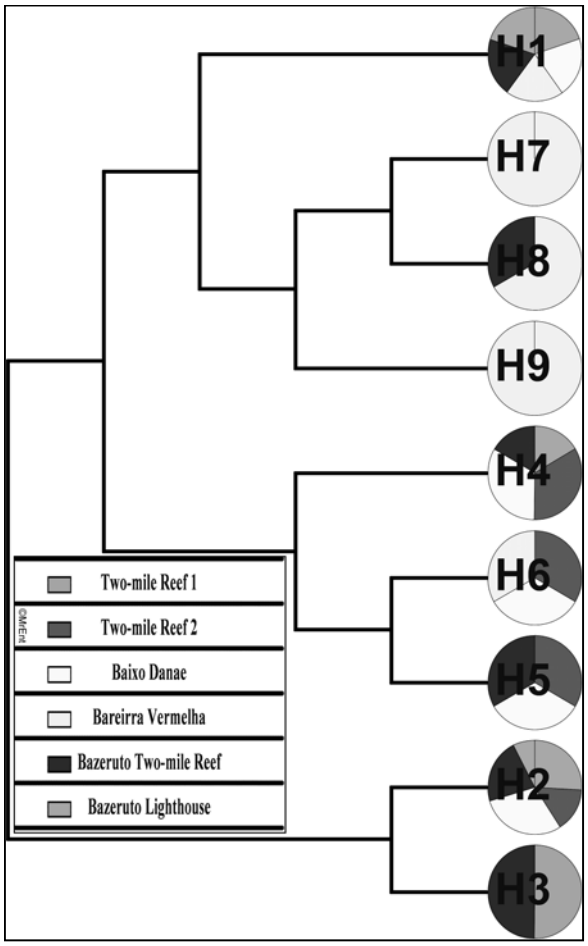

Figure 2 Minimum spanning network shows relationships between *A. austera* nuclear intron haplotypes and collection localities in the south-west Indian Ocean.

Using mismatch distributions (Fig. 3) we found that the Inhaca Island population of BV may have established equilibrium in terms of growth, in contrast to other populations (Rogers and Harpending 1992).

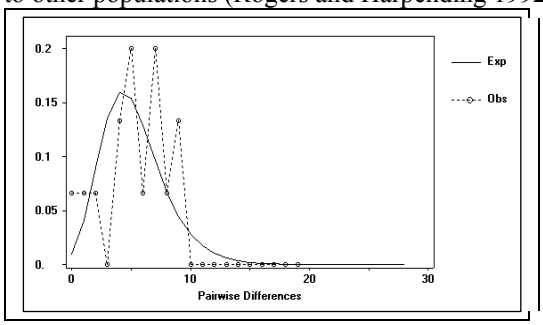

Figure 3. Pairwise mismatch distribution for population BV, generated in DNAsp (Rozas *et al* 2003).

Upon removing BV from further analyses, we found Nm = 3.87 and γst = 0.06, indicating that the remainder of the populations were less differentiated

from one another than they were from BV (Hudson *et al.* 1992). Genetic fixation indices calculated in AMOVA for *P. daedalea* were not significant. The proportional inter-population gene diversity was found to be γst = 0.29 with Nm = 0.63. We found evidence for a minimum of two recombination events within the ITS region of *P. daedalea*.

Discussion

Nuclear genetic markers from *A. austera* and *P. daedalea* showed markedly different levels of variation amongst the populations sampled, which may be attributed to the different evolutionary constraints under which they evolve. Analysis of sequence variation in the intron that was used to compare populations of *A. austera* showed that populations regularly exchange genes, with the exception of the population of Barreira Vermelho (BV), which may be isolated from the other local populations. Genetic diversity (which may be equated to nucleotide diversity) was particularly high (π = 5.8) within the BV population in comparison with other local populations (Tab. 2). This may be a consequence of the predominant current patterns offshore of Maputo Bay and the Delagoa Bight (Fig. 1) (Lutjeharms 2006), which circulate bay waters in a clockwise eddy. These local currents may inhibit the spread of propagules out of this breeding population. Pairwise F_{ST} values indicated that BV was significantly distinct from other populations sampled. Further, other *A. austera* populations in the study appear to differ in growth pattern from those at BV (Fig. 3). Once BV was removed from analyses, further tests of variability demonstrated that the remaining *A. austera* populations were panmictic. Haplotypes were shared widely between populations and there was no evidence of reciprocal monophyly (Fig. 2). This was similar to results of previous regional work on *Pocillopora verrucosa,* which showed local panmixia (Ridgway *et al.* 2001).

Local *A. austera* populations are expected to rely on migrants from the north to maintain levels of genetic diversity, in a similar fashion to that reported for *Pocillopora verrucosa* (Ridgway *et al.* 2008). This may be confirmed by a larger scale analysis which includes more populations from this region. With longer-lived coral species, such as *P. daedalea* (in comparison to *A. austera)*, it is possible that there may be enough migration to sustain a high level of genetic homogeneity throughout a larger area, as was found for *Plesiastrea versipora* in the western Pacific (Rodriguez-Lanetty and Hoegh-Guldberg 2002). However, although *P. daedalea* populations are well differentiated (γst = 0.29), the ITS region is notoriously difficult to work with (Lam and Morton 2003; Vollmer and Palumbi 2004, Mangubhai and Souter 2007) and regions with such high recombination rates may not yield conclusive results at this scale. Thus, other than to encourage further research using more conclusive molecular markers and larger population sizes, little may be drawn from analyses of the ITS region of *P. daedalea* in this study.

Southward movement the water is very gradual ($0.05ms^{-1}$ south) in the north of the study area, but the current is fast flowing from between Inhaca and Maputaland ($1.5ms^{-1}$ south, Lutjeharms 2006). These currents do not necessarily preclude movement of propagules in a northerly direction in nearshore water movement. East African reefs are thus unlikely to be connected to the same extent amongst all genera considering the different reproductive strategies amongst local scleractinians (Mangubhai and Harrison 2006). Population genetic studies of species with very different life strategies, such as *A. austera* and *P. daedalea,* will help to shed light on this issue, especially if fine-scale variability within and between populations is measured. Future research in the SWIO region would benefit from employing molecular markers which display the high resolution necessary to detect this variability.

Abstract

Despite active conservation measures, slow recovery of Queen conch (*Strombus gigas)* is a growing concern in the Caribbean. Conventional expectations presume that *S. gigas* populations are largely connected, but we present results of veliger larval drift and survival from the Yucatan peninsula that suggest otherwise. Spatial patterns of observed and simulated larval stages during the reproductive season revealed segregation of the Mexican populations, with high levels of larval retention on Campeche Bank contrasted to variable larval transport along the Mexican Caribbean coast into the Yucatan Current, and eventually into the Loop Current. Consequently, the probability that *S. gigas* larvae originating from the Mexican Caribbean settle to Alacranes Reef is null. In addition, the Alacranes *S. gigas* population is not source to Florida, while a small fraction of larvae produced north of the Mexican Caribbean coast periodically reaches the Florida Keys (*ca.* 1-12%) and Cuba (0.1-4%), while very few individuals reach the NW Bahamas (0-0.5%). Although this long-distance dispersal may not be sufficient to replenish the downstream populations, gene flow could prevent differentiation of the Florida Keys and Mexican Caribbean Queen conch populations. This study constitutes a first step in understanding Queen conch metapopulation structure and calls for more local actions for the recovery of Mexican populations.

Keywords: Queen conch; larva; population connectivity; biophysical modeling; isolation

Introduction

The Queen conch, *Strombus gigas* (Mollusca, Gastropoda: Strombidae), has been a significant marine resource for the Caribbean since pre-Columbian times. Since the 80's, commercial catch has increased in response to the international market. Consequently, several stocks have been reduced to levels where the population can no longer recover. Queen conch was included in 1992 in the Convention on International Trade in Endangered Species (CITES) of Wild Fauna and Flora, and in 1994 and was added to the International Union for the Conservation of the Nature's (IUCN) Red List. Following the pattern of other Caribbean countries, a decline in abundance in the 80's led to the closure of the Yucatan fishery (Pérez-Pérez and Aldana-Aranda 2000). Presently, there is a temporal ban during peak spawning season, from March to October, a harvest quota for Chinchorro Bank and Cozumel, and a minimum capture size. In spite of these measures, for the most part the distribution of Queen conch in the area remains confined to marine protected areas. Given similar conservation measures for the area, one might expect a uniform response from the population, but this does not appear to be case, as evidenced by discrepancies between Alacranes Reef on Campeche Bank, and Chinchorro Bank situated on the Caribbean coast (Aldana-Aranda et al. 2003). The population of *S. gigas* in Alacranes Reef was almost depleted after 1988 and recent studies still report relatively low abundances there (Pérez- Pérez and Aldana-Aranda 2000). In contrast, despite lack of enforcement, the population situated at Chinchorro Bank has remained relatively stable. These observations suggest that Alacranes Reef may be disconnected from other populations along the Caribbean coast. Effective management of these populations could be greatly enhanced by better enforcement but also by understanding of larval movements. According to a theory developed by Stoner (1997), currents carrying larvae from the Yucatan Peninsula to the Bahamas and Florida could also provide larval drift between the Mexican Caribbean coast and the North Yucatan Peninsula. Studies of the abundance of larvae have been carried out in Florida and the Bahamas (De Jesús-Navarrete and Aldana-Aranda 2000) with the intention to protect the larval sources of *S. gigas*. This study examines Queen conch larval transport with the goal of testing Stoner's null hypothesis that geographically separated *S. gigas* populations are linked. Our major objectives are to describe patterns of *S. gigas* larvae around the Yucatan Peninsula and

their potential transport to Florida, the Bahamas, and Cuba, and identify likely larval sources in the Yucatan Peninsula. We use both field studies and biophysical modeling coupling currents with *S. gigas*' life history traits. We use field observations to corroborate the numerical model predictions, and then probabilistic simulations to estimate larval linkages.

Study Area

The study region was limited to test the null hypothesis that Queen conchs in Mexico form a single

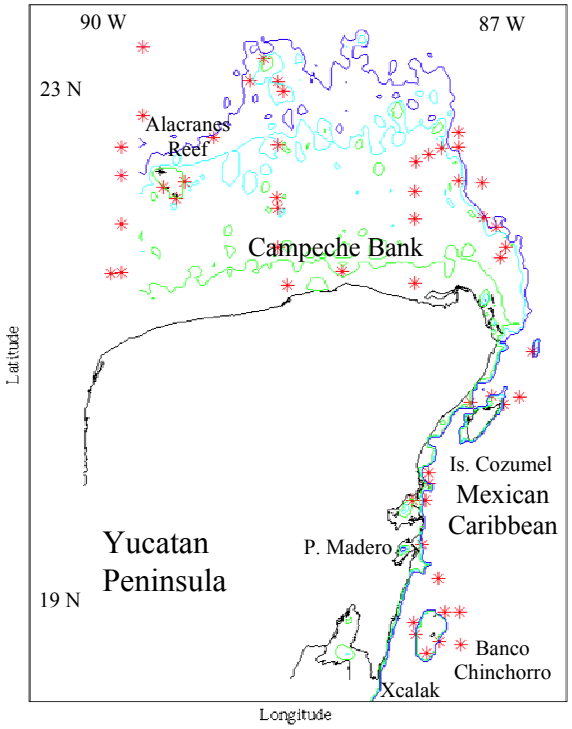

Figure 1. Sampling sites (red stars) in the Yucatan Peninsula during 2001. Green, cyan, and blue lines represent isobaths 20, 60, 100 m, respectively. The Alacranes lagoonal reef is located at the edge of the 60 m isobath on the west of the Campeche Bank, sole home of the Queen Conch on the Bank.

population. The Yucatan Peninsula has two distinct marine regions: (1) the Mexican Caribbean (MC) coast with a narrow shelf, bordered by back reef lagoons, shallow bays and banks; (2) the Campeche Bank with a wide shelf and a single small bank, the Alcranes Reef (AR, Fig. 1). The Caribbean Current veers northwestward as it impinges the margin of the Yucatan peninsula and becomes the Yucatan Current, which enters the Gulf of Mexico as the Loop Current and exits through the Florida Straits as the Florida Current. In addition, a large cyclone-anticyclone pair south of Cuba feeds occasionally into the Yucatan Current. Transport in the Yucatan channel is characterized by the main surface inflow into the Gulf of Mexico and deep reverse outflows along the Cuban and Mexican sides (Cherubin et al. 2005). On the Mexican side, deep outflow occurs at the level of the cape of the continental margin (22°N, 86.5°W, nearby the group of stations 38-41 in Fig. 1), forming a convergence zone near the surface. On average, the Yucatan Current flow is weaker from November to February and becomes stronger from May to August. Spawning of *S. gigas* occurs from March to October, with 1-6 spawning events per female producing benthic egg masses (Pérez-Pérez y Aldana-Aranda 2000). Veliger larvae become competent on average at 20 days after hatch (dah), but metamorphosis can occur anywhere between 12-60 dah. Similarly plastic, the average pelagic larval duration is 30 d. Veliger are usually found in the upper 5 m of the water column, but are capable of vertical migration.

Material and Methods

Observations

Plankton was sampled at 83 stations during oceanographic surveys of the Marine Secretary from the north of Chuburná Puerto and Cabo Catoche during March, July, and October of 2001. Sea surface temperature and salinity were recorded. Near surface (1m) plankton tows were made with a Bongo net of 0.61 m diameter and 302µm mesh size. Tow durations were 15 min at 1 $m.s^{-1}$ and volume filtered was measured using a calibrated flow-meter. Samples were preserved at sea in a 5% neutral formaldehyde-seawater solution. In the laboratory, samples were sorted using a dissecting microscope (20x). *S. gigas* were identified following Davis et al. (1993). Shell length (SL) was measured with a calibrated ocular micrometer and veligers were divided in two size classes and aged based on laboratory growth rates (Brito-Manzano and Aldana-Aranda 2004): pre-competent larvae < 700 µm SL, ≤ 20 days; competent larvae > 700 µm LS, ≥ 21 days.

Biophysical Model and Simulations

Larval transport was simulated using daily archived velocity fields of the North Atlantic HYbrid Coordinate Ocean Model (HYCOM; 10 m coastal boundary; 1/12° horizontal resolution; http://hycom.rsmas.miami.edu) coupled to a particle tracking algorithm. The code described in (Paris et al. 2007) integrates adult spawning strategies, conch larval traits, and recruitment habitat. Pre-competent particles (or virtual larvae) were passive, but at competency they could sink if their path crossed suitable nursery habitat. However, if the particle reached maximum competency without finding habitat, it was removed from the system. There were to many assumptions related to introducing larval mortality in the model due to lack of data on larval survivorship while egg mass survival tend to change throughout the spawning season (Aldana-Aranda et al. 2003). Thus mortality was not accounted for,

which, on the other hand, tends to overestimate long distance dispersal (Cowen et al. 2000), specifically when pelagic duration is variable (Paris et al. 2007). The habitat data was developed using reef locations provided by the Millennium Coral Reef Mapping Project (http://imars.usf.edu/corals) buffered at 5 km

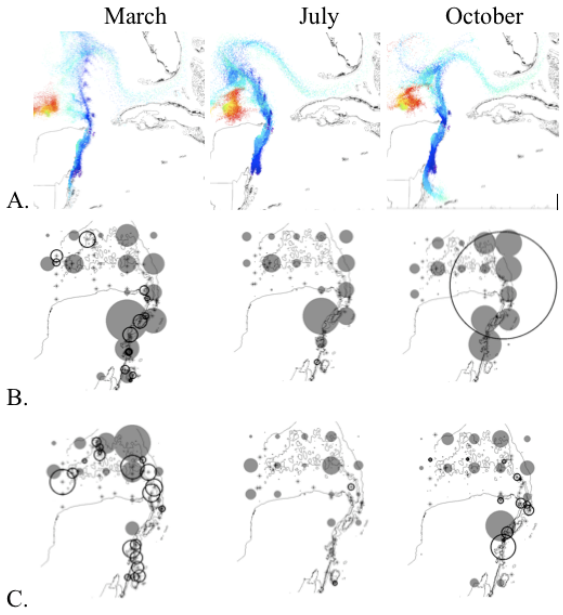

Figure 2. A) Simulated dispersal of *S. gigas* larvae released during the first day of March, July, and October from 2 spawning locations. Color gradients indicate dispersal time from Alacranes Reefs (yellow » red = post-hatch » competent larvae) and along the Mexican Caribbean (blue » cyan). B) Modeled (grey dots) and observed (black circles) distribution patterns of pre-competent (1-20 days old, size < 700 µm) *S. gigas* larvae. C) Modeled and observed patterns of competent larvae (21-40 days old, size > 700 µm). The virtual larvae have a pre-competent, passive period of 20 d and a maximum pelagic duration of 40 d.

and split using a tolerance level of 10 km. A total of 60, 5, 50, and 355 reef polygons shaped the MC, AR, FLK, and Bahamas respectively. In a first scenario (*Model 1*) virtual released during March, July and October from the 83 stations sampled in 2001 were done to validate the biophysical dispersal model by comparison of observed and modeled larval distributions. Particle release at each station was scaled by observed densities, while particle 'age' at release corresponded to the mean developmental stage of the sample. In a second probabilistic scenario (*Model 2*), a series of 1000 particle releases were initiated in the 0-20 m layer with a monthly frequency from February to October at all 65 locations (60 MC, 5 AR) within the Yucatan Peninsula region (Fig, 2A). The source and receiving location for individual particles was recorded to build connectivity matrices and estimate the probability of larval exchange between and among regions.

Results

Spatio-temporal abundance and size of veligers

Observations on the North Yucatan Shelf: during March, 50% of the 31 stations sampled (1-37, Fig. 1) yielded 68 larvae, with a maximum density of 1.8 • 10^{-1} m^{-3} at station 4, about 100 km south of Alacranes Reefs (Fig. 2C). Mean density was 0.28•10^{-1} m^{-3} and size ranged from 520-990 µm (mean 774 µm), with a tendency towards competent larvae. In July, 17% of the 12 sites yielded few pre-competent larvae (i.e. 4 larvae, maximum density 0.07•10^{-1} m^{-3}, mean size 512 µm). In October, 30% of the 17 stations sampled yielded 18 larvae with a maximum density of 0.1• 10^{-1} m^{-3} at station 27 north of Cabo Catoche. Most larvae

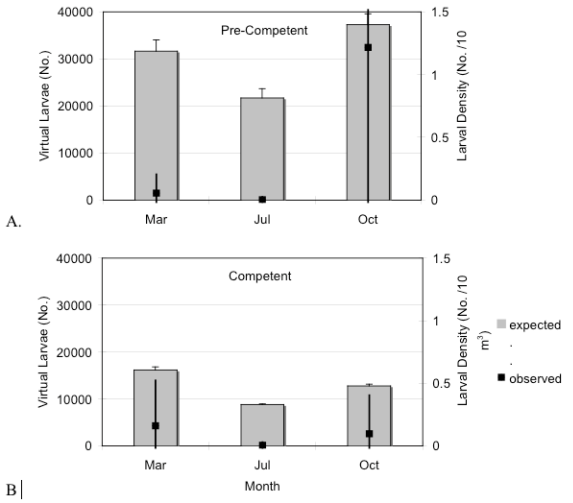

Figure 3. Average temporal trends of pre-competent and competent conch larvae around the Yucatan Peninsula from A) point observations at stations (black squares) and B) modeled distributions (filled grey bars) during one year. Mean and standard deviation are calculated from the stations sampled and the binned distribution (black circles and filled grey filled, respectively, in Fig 2). Note similar trends betwen modeled and real abundances with higher variance in observations (i.e. more spatial patchiness).

were competent with a size range of 670-970 µm (mean 873 µm).

Observations along the MC Coast: during March 2001, 57% of the 30 stations sampled (stations 38-83, Fig. 1) yielded 82 larvae with a maximum density of 0.9•10^{-1} m^{-3} at station 66 (Fig. 2C). Size ranged from 350-990 µm with a tendency towards early stage larvae (mean 645 µm). Mean density was 0.17•10^{-1} m^{-3}. In July 17% of the 18 stations sampled yielded only 6 larvae. Similarly to the North Yucatan Peninsula, mean density was very low (0.01• 10^{-1} m^{-3}) but larvae were competent (mean size 825 µm, range 680-970 µm; Fig. 2C). In October, 60% of the 16 stations sampled yielded the largest number of larvae (n = 1642) with a maximum density of 43.2•10^{-1} m^{-3}

in a single patch of 1402 larvae at station 40, northeast of Holbox Island at the cape where (Fig. 2B). Catches were composed of all stages as sizes ranged from 520-990 µm (mean size 783 µm, mean density $1.93 \cdot 10^{-1}$ m-^{3}).

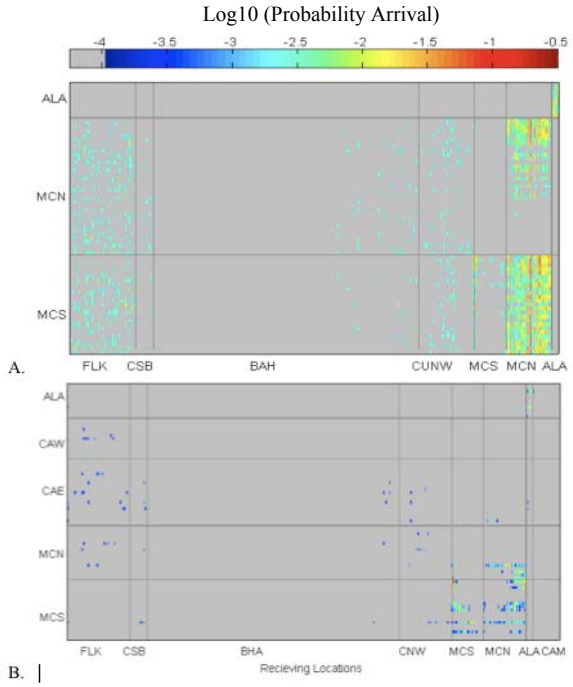

Figure 4. Connectivity matrices between *S. gigas* populations from the Yucatan Peninsula, Florida Keys, Bahamas, and NW Cuba estimated from A) probabilistic scenario (Model 2): homogeneous monthly (Feb-Oct) spawning events from 65 reef locations of the Yucatan and B) predictive scenario (Model 1): scaled production, initializing larval transport from observed distributions of larvae. Each matrix elements is the probability of larvae from source *i* (Y-axis) moving to destination *j* (X-axis) over the reproductive season. Color-code indicates levels of connectivity, grey is no larval exchange. The source and receiving locations are: Alacranes (ALA); Mexican Caribbean S (MCS, Ascension Bay to Chinchorro Bank); Mexican Caribbean N (MCN, Ascension to Contoy); Campeche Bank East & West (CAM, CBE, CBW); Florida Keys (FLK); CaySal Bank (CSB); Bahamas (BAH); NW Cuba (CUNW).

Comparison of observed and modeled distributions

Observations and predictions agree well early in the reproductive season (i.e. March), when early stages are found in both locations with an noticeable separation between the MC the western part of Campeche Bank, near Alacranes Reef (Fig. 2B). More advanced larvae are predominant in the North Yucatan (Fig 2C). This is an indication that both areas are sources. Monthly patterns are also well predicted by the model, with lower densities during July (Fig. 3), when currents along the MC are swifter (Tang et al. 2005). In addition to higher dispersal, atmospheric conditions may have been unfavorable for the larvae. Indeed, veliger are presumably more abundant near the surface during calm seas (Barile et al. 1994) but they sink in turbulent conditions. This would have affected regional-scale sampling. During October, *S. gigas* densities increased in both model and predictions, but observations were more patchy with 1402 larvae caught a single station. This rare catch was composed of a mixture of larvae from 10-30 dah (520-890 µm), indicating that they have been accumulating in that area for more than 10 days. Larval vertical behavior in convergence zones could create large patches of larvae. The model did not predict accumulation of larvae in a small area such as through eddies. Yet, virtual larvae from 20 to 30d old were accumulated along a strong frontal convergence (Fig. 2B). According to the model, this large larval patch could have contributed to recruitment during November in the Dry Tortugas, but not as an unusual larger recruitment peak. When the model is run in a probabilistic mode with a series of temporal releases from all possible source locations (Model 1) rather than predictive (Model 2), the spatial pattern of larval densities is re-established. Thus we are confident that the biophysical model is consistent with the observations and can be used to estimate larval exchanges between regions.

Modeled Dispersal around the Yucatan Peninsula

Larval dispersal from the MC coast is variable and extends south to the northern atolls of the Belize Barrier Reef, and north to the lower FLK (Fig. 2A). On the other hand, dispersal from the North Yucatan is limited and less variable with high retention around AC. In July, higher northward transport of the Yucatan Current in the simulations produced lower larval densities along the eastern edge of the Peninsula (Fig. 2C).

Larval exchange between sub-regions

There is high connectivity within sub-regions and clear isolation of AR (Fig. 4). The MC export a small fraction of total recruits to FLK (12%), 4% to NW Cuba, and <1% to 16 polygons of the 355 polygons representing the Bahamas, none to AR. Most (82%) settlement was local, the southern part of the MCS being a large source to the north (MCN, Fig. 4).

Discussion

The planktonic nature of the Queen conch larvae suggests that ocean currents would quickly cause panmixis over large spatial scales and prevent isolation of populations. However, slow recovery of the Queen conch in the Caribbean, especially in AR and FLK, contradicts this panmixis hypothesis. While genetic studies do not show population structure in the Caribbean (Sobel et al. 1988), this study shows far greater isolation than hypothesized by Stoner (1997). As a consequence, *S. gigas* populations could develop genetic differences that can only be resolved by using fast evolving genes (e.g. Baums et al. 2005). This

study suggests that AR is not a source for the Floridian *S. gigas* populations. The Lower FLK may occasionally receive a small fraction of recruits from the MC (i.e., 1-12%, Fig. 3). The strength of the Yucatan Current as well as the northward intrusion of the Loop Current seems to control the level of exchanges. However, this long distance dispersal may not sustain the FLK populations. In fact, the FLK populations of *S. gigas* have been under a total catch ban since 1985 but have not shown signs of recovery indicating that subsidies are not sufficient to sustain the population. The southern MC appears to be an important source of *S. gigas* larvae and a corridor for populations located on either side. De Jesús-Navarrete and Aldana-Aranda (2000) found a high percentage (89%) of early stages larvae in Chinchorro Bank, and hypothesized that this site is a potentially important source of veliger *S. gigas* to other sites of the Quintana Roo coast, and possibly to Florida. We do not find evidence that Chinchorro Bank contributes recruits to FLK, but it is most probably a source for the MC coast. Indeed, the model indicates that potential source locations of *S. gigas* for the MC are located from Chacala and Tulum to Xcalak, including Chinchorro Bank, and from Puerto Madero and Majahual to Xcalak. However, locations between Puerto Madero and Majahual to Xcalak seed only the northern portion of Quintana Roo. De Jesús-Navarrete and Aldana-Aranda (2000) also indicates that competent larvae were found in Cayo Lobo, south of Chinchorro Bank and assumed that they might have come from distant sources in Belize. Yet, throughout the *S. gigas* reproductive season, alongshore currents can reverse, allowing larval drift from Quintana Roo coast towards the south, including part of the Belize Barrier Reef (Fig. 2A). Detailed larval linkages are worth investigating further to map networks of *S. gigas* populations within the Mesoamerican region.

Risk of species extinction from an unpredictable physical environment and/or strong interactions between species is minimized by metapopulation structure (Harrison and Taylor 1997). This may be the case for the lower Florida Keys population, which is weakly connected with the MC. Indeed, if retention is a common phenomenon for this species, then the exchange rate of veligers would be low enough to fit the metapopulation assumptions (Harrison and Taylor 1997). The latter explains the fact that the Queen conch has a wide distribution of fragmented populations in the Caribbean and yet may maintain genetic continuity. Thus, conservation measures should take into account local networks of sub-populations. Isolated populations, which have a higher risk of extinction, should be protected and managed separately. In summary (1) the populations from the North Yucatan Peninsula and the Mexican Caribbean are segregated, with major isolation of the Alacranes Reef, while spawning entities along the Mexican Caribbean are highly inter-connected; (2) This study does not support Stoner's hypothesis of long distance larval linkages between Queen conch populations in the Caribbean. Simulations reveal a weak connectivity of the Mexican Caribbean with the Lower Florida Keys. Yet, there are no significant exchanges with the Bahamas (i.e., 2-3 order of magnitude lower recruitment levels in < 4% of the Bahamian habitat) and clear isolation of the North Yucatan Peninsula; (3) although the biophysical model reproduces trends in larval densities, there is mismatch in snapshots of spatial distributions. Biological factors such as aggregation in fronts, sinking in turbulence and mortality (Paris et al. 2007) must play a role in determining absolute levels of settlement.

Abstract. Genetic variation was analyzed to determine whether two morphotypes, a massive and columnar form, of *Porites panamensis* found together in the Gulf of California (GC) were genetically differentiated. Levels of genetic variation were similar between morphotypes and no fixed alleles were detected between them. Levels of sexual reproduction were high, as indicated by ratios N_G:N 0.76-1.00 and G_O:G_E 0.71-1.00 for both morphotypes. Analysis of Molecular Variation (AMOVA) indicated the greatest significant genetic variation within populations (97.85%) and among populations within morphotypes levels (2.63%), but not among morphotypes (-0.47%, p = 0.6826). Mean significant F_{ST} values for columnar (F_{ST} = 0.024) and massive (F_{ST} = 0.043) suggest that both morphotypes had moderate genetic structure within their populations. The number of migrants per generation (N_em) showed differences within morphotype populations (columnar 4.65-31 and massive 2.65-9.75). The lower genetic differentiation among morphotypes indicates that it is likely that they frequently interbreed. However, we observed a genetic differentiation among the populations of the morphotypes of *P. panamensis* in the north and central part of the GC, while in the south of the GC the populations of both the morphotypes are more similar and may constitute a population that is more genetically homogeneous. North-central coral communities from the GC are characterized by extreme temperature and nutrients conditions and adaptation to this stress environment may be reflected in our genetic data.

Key words: Species complex, genetic structure, Scleractinian coral, population genetics.

Introduction

The genus *Porites* Link 1807 has a cosmopolitan distribution and comprises around 60 of the world's main reef-building species (Veron 2000). It has proved difficult to efficiently delimit the taxonomic position of several species of this genus because of their considerable morphological diversity, resulting in overlapping of characters among taxa (Weil 1992; Garthwaite et al. 1994; Veron 2000). In the Gulf of California (GC), a complex of species presents this problem, involving the nominal taxon *Porites panamensis* Verrill 1866. This coral exhibits four colonial morphologies that were described originally as different species: massive (*P. panamensis, sensu stricto*), encrusting (*P. californica*), columnar (*P. nodulosa*) and branching form (*P. sverdrupi*). These nominal species were considered lately to be ecotypes of different depths and synonyms due the high morphological variation in the genus (Squires 1959; Wells 1983). However, morphometric and genetic studies indicate that at least the ramified form (*P. sverdrupi*) is a valid and endemic species of the GC (López-Forment 2003; López-Pérez et al. 2003; Forsman et al. 2006). The columnar and massive morphologies of *P. panamensis* have presented slight differences in the number of pali of their corallites (Ketchum and Reyes-Bonilla 2001). In field, differences between these forms were found in their susceptibility to algal colonization, which could mean that the columnar morphotype has a survival advantage over the massive (Paz-García and Reyes-Bonilla 2006). In vertical distribution, the massive morphology is from 1 to 30 m of depth and the columnar one is present from 1 to 5 m (López-Pérez et al. 2003; Paz-García and Reyes-Bonilla 2006). In addition, the massive morpotype is distributed from the GC to Colombia, while the columnar one is observed only inside the GC and Revillagigedo's islands (Ketchum and Reyes-Bonilla 2001; Paz-García and Reyes-Bonilla 2006). It is still unidentified if these differences between morphotypes are due the morphological plasticity or if they correspond to different species. Allozyme electrophoresis studies have been showed useful to distinguish species

boundaries in the genus *Porites* (Weil 1992; Garthwaite et al. 1994) and to assess the contribution of reproductive mode (sexual vs asexual) within the populations (Ng and Morton 2003; Nishikawa and Sakai 2005). Furthermore, the presence of different species or the morphology itself by means fragmentation could show differences between morphotype populations along the GC. The aims of this study were to (1) determine if the columnar and massive morphotypes of *P. panamensis* were genetically differentiated to clarify the taxonomic position of this group of morphospecies, (2) describe the genetic variation between the morphotype populations, (3) determine the contribution of reproductive mode (sexual vs asexual) within morphotype populations of *P. panamensis* in the GC.

Material and Methods

Field Work. In August of 2004, we collected 55 and 58 coral fragments for columnar and massive morphotypes, respectively, using SCUBA. The specimens were collected in one to three coral communities (1-9 m of depth and over an area of 400 m^2) within each collection area. The collection areas were in the GC, Mexico (Fig. 1): Bahía de Los Ángeles (BLA), Isla San Marcos (ISM), Bahía Concepción (BCO) and Sourth of Bahía de La Paz (BLP). The coral fragments were frozen in liquid nitrogen and transported to the Biochemistry Lab from the Centro de Investigaciones Biológicas del Noroeste at La Paz, BCS, Mexico where they were stored at –80°C.

Allozyme Electrophoresis. One or two ml of blastate was obtained with a gun of air pressure from SCUBA tank and rinsed with seawater. The blastate still contained zooxanthellae and although these possess own genetic material, in previous studies it has been observed that not affect the genetic analysis by allozyme on corals (Stoddart 1983; Willis and Ayre 1985). However, the microalgae symbionts were isolated of the host tissue by centrifugation to minimize the possibility of contamination (Stoddart 1983; Weil 1992). One milliliter of blastate was centrifugated at 2600 *g* for 4 min at 4°C. The supernatant was placed in vials and mixed with 40 µl of Stoddart's buffer modification (Stoddart 1983; Weil 1992). Zooxanthellae enzymes extracted from coral tissue did not appear on our gels. The concentration of total proteins from each sample was analyzed by Bradford's method (Bradford 1976) and 25 µg of sample was used for the analysis. Four enzyme systems were used: *Mdh* (E.C.1.1.1.37), *Leu-leu*, *Leu-tyr* and Leu-gly-gly peptidases (E.C.3.4.11). Allozyme analysis was carried out using the method of Polyacrilamide Gel Electrophoresis (PAGE) by discontinuous gel system in native conditions (Laemmli 1970; Manchenko 1994).

Statistic analysis. Genetic variability (Swofford and Selander 1981), $N_G{:}N$, and $G_O{:}G_E$ (see Table 1 legend) were calculated for each population of both morphotypes (Stoddart and Taylor 1988). Unbiased genetic distances (D) were used for cluster analysis (Nei 1978). We performed an analysis of molecular variance (AMOVA) to compare genetic similarity between the morphotype populations, P-values were calculated from a random permutation test with 16 000 replicates (Excoffier et al. 1992). The level of genetic heterogeneity and gene flow among morphotypes were estimated by F_{ST} and the average number of migrants per generation (*Nem*), respectively. We calculated pairwise F_{ST} estimates between each pair of populations (within and among population morphotypes). F_{ST} were tested for difference from zero permuting (10 000 replicates) alleles between samples with exact G-test (Goudet *et al*. 1996), as implemented in FSTAT v. 2.8 (Goudet 1995). We applied a sequential Bonferroni correction to reduce the chance of type I errors (Rice 1989).

Results

No fixed alleles were detected between morphotypes. The mean number of alleles per locus at each location ranged from 1.9 to 2.4 for the columnar morphotype and from 2.1 to 2.3 for the massive one (Table 1). The observed heterozygosities were slightly higher that the expected under Hardy–Weinberg equilibrium in all populations, ranging from 0.331 to 0.486 for columnar morphotype and 0.331 to 0.529 for massive morphotype (Table 1). The ratios $N_G{:}N$ (0.76-1.00) and $G_O{:}G_E$ (0.71-1.00) for both morphotypes indicate a high rate of sexual reproduction and that this strategy is the most important in the maintenance of their populations in the GC (Table 1). AMOVA indicated the greatest significant genetic variation within populations (97.85%, $p<0.001$) and among populations within morphotypes levels (2.63%, $p<0.001$), but not between morphotypes (-0.47%, $p = 0.6826$). The values of Nei´s (1978) unbiased genetic

distances within morphotype populations, ranged from 0 to 0.020 and 0 to 0.050 for columnar and massive morphotypes, respectively (Table 2). The values of genetic distance between samples of different morphotypes ranged from 0 to 0.047. Cluster analysis showed three groups by geographical proximity in the GC: one group included both northern morphotype populations, a second group formed by central massive populations, and center-south populations of the columnar with the southern population of the massive morphotype as another cluster (Fig. 2).

Table 1. Genetic variability and relative contribution of the sexual and asexual reproduction of populations of columnar and massive morphotypes of *P. panamensis* from the GC. *N* number of individual colonies at each population, N_G number of unique genotypes observed at each population, G_O and G_E observed and expected genotypic diversity, respectively. Mean significant F_{ST} values after Bonferroni correction were observed for columnar (F_{ST}=0.024, p<0.01) and massive (F_{ST}=0.043, p<0.01) morphotypes. Pairwise F_{ST} estimates revealed no significant differences between the populations of both morphotypes in the same location, but significant differences were observed between the populations of BLA from both morphotypes and the rest of the GC (Table 2). N_em showed differences between morphotypes; the columnar presented higher values (4.65-31) among its populations in comparison with the massive (2.65-9.75). N_em between populations of different morphotypes ranged from 3.27 to 27.52.

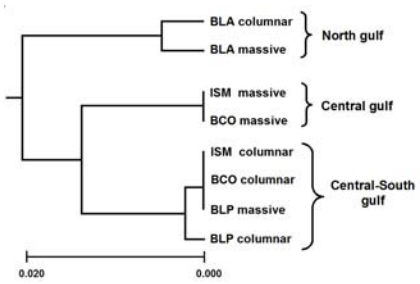

Figure 2: UPGMA dendrogram showing the populations of columnar and massive morphotypes of *P. panamensis* in the GC based on Nei´s (1978) unbiased genetic distance.

Discussion

No fixed alleles were detected between columnar and massive morphotypes of *P. panamensis* and AMOVA indicated that the variation was not significantly partitioned between morphotypes (-0.47, p=0.6826). In addition, the Nei´s (1978) unbiased genetic distance between morphotypes was 0.0009. These data suggest that both morphotypes interbreed frequently and are likely to be the same species. However, slight genetic differences were observed between morphotype populations. The columnar morphotype had lower genetic differentiation within populations (D <0.020) than the massive one (D <0.050). The values of genetic distance within populations of the columnar morphotype are similar to those reported in literature for populations with slight genetic differentiation, such as *Platygyra sinensis* (D <0.008; Ng and Morton 2003) and *Mydedium elephantotus* (D <0.015; Yu J-K et al. 1999). The values of genetic distance obtained within populations of the massive morphotype and among the populations of the morphotypes are more similar to the distances reported for those species that possess genetic structure in their populations such as *Goniastrea aspera* (D <0.040, Nishikawa and Sakai 2005) and *Pocillopora damicornis* (D < 0.066; Adjeroud and Tsuchiya 1999).

The dendrogram of Nei´s unbiased genetic distance showed three groups of populations clustering mostly by geographical vicinity (Fig. 2). This pattern showed the subdivision exists among the populations of the morphotypes of *P. panamensis* in the north part and central of the GC, while in the south of the GC the populations of both the morphotypes are more similar and may constitute a population that is more genetically homogeneous. Mean significant F_{ST} values observed in both morphotypes (F_{ST} > 0.024, p<0.01) suggest that those have a genetic structure within their populations along the GC. Genetic structure in both morphotypes can be explained by the

brooding larvae of *P. panamensis* that are recruited to some few meters of the parental colonies (Glynn and Ault 2000). Pairwise F_{ST} estimates revealed no significant differences between the populations of both morphotypes in the same location, but significant differences were observed between the populations of BLA from both morphotypes and the rest of the GC (Table 2). Studies carried out with diverse taxa have suggested the north area of the GC is a different biogeographic region; it has based on the pattern of distribution of species, salinity differences, temperature, tide, high eutrophic conditions, to the population subdivision and the reduction of the genetic flow in marine invertebrates and fishes (De la Rosa-Vélez et al. 2000; Riginos and Nachman 2001, Halfar et al. 2004). This difference may be due to combined effects of biogeography, geographical distances, and habitat discontinuity that could result in different evolutionary histories among populations (De la Rosa-Vélez et al. 2000; Riginos and Nachman 2001). In addition, the coral community of *P. panamensis* from Bahía de Los Angeles is characterized by temperatures extremes (ranging from 14°C to 30°C), lower penetration of light (-9m), the highest values average in chlorophyll in coral communities of high latitudes (2.2 mg Chl a/m), high content of phosphates (1.8 µmol/l) and nitrates (9.9 µmol/l) that affect the growth and coral development (Halfar et al. 2005). This community can be adapted to temperature stress and nutrients (Halfar et al. 2005), and may be reflected in our genetic data. The morphotypes showed differences in N_em in populations with separation of 750 km; the columnar form presents three times higher number of migrants within its populations in its maximum values in comparison with the massive one (4.65-31 vs 2.65-9.75). Similar values of migrants per generation have been estimated in populations with separation of 1700 km for broadcast spawners (4.8-24.8) and brooding species (1.4-19; Ayre and Hughes 2004). However, gene flow among populations is affected by diverse factors such as the reproductive mode of the studied species, overlapping generations, dispersal ability, habitat discontinuity, available space for recruitment, oceanographic conditions and isolation by distance (Stoddart 1983; Ayre and Hughes 2004).

Previous studies of allozyme electrophoresis in coral species have revealed populations that reproduce mainly sexually, asexually or with a mix of reproductive mode (Stoddart 1983; Yu et al. 1999; Nishikawa and Sakai 2005). Our data show that asexual reproduction (e.g. from fragmentation, budding, or fission) had little influence on the maintenance of the populations of *P. panamensis*, which is consistent with ecological studies (Glynn et al. 1994; Reyes-Bonilla and Calderón-Aguilera 1994). High ratios of N_G:N = 1 and G_O:G_E > 0.719 suggest that sexual reproduction in both morphotypes of *P. panamensis* is the most important means of maintaining their populations in the GC. These results are consistent with life history characteristics of the columnar morphotype in BLP, which can brood larvae over the whole year (Mora-Perez 2005). In addition, the population BLP of the columnar morphotype presented some clonal multilocus genotypes (Table 1). This suggests that this population is occasionally subject to reproduction via fragmentation, which is consistent with its colonial morphology and the incidence of hurricanes in the south of the GC. The absence of colonies with clonal multilocus genotypes in the massive morphotype is also consistent with its colonial morphology that is less likely to fragment. The generally high frequencies of unique multilocus genotypes in most populations of both morphotypes of *P. panamensis* may be due to diverse habitats and oceanographic conditions along the GC (López-Pérez et al. 2003; Halfar et al. 2005; Paz-García and Reyes-Bonilla 2006), to the high frequency of sexual reproduction and recruitment during the whole year (Mora-Perez 2005), or to the type and the frequency of moderate environmental disturbances (i.e. ENSO events and hurricanes) that may favor genotypic diversity in sexually reproducing coral communities (Coffroth and Lasker 1998). Our data suggest a higher sexual reproduction rate for massive morphotypes than columnar, however there are no reproductive studies of the massive morphotype in the GC. Studies carried out in Jalisco and Oaxaca showed that the massive morphotype reproduces during the warm months (May to September; Vizcaíno-Ochoa 2003; Rodríguez-Troncoso 2006). If this occurs in the GC, differences in the reproductive season among morphotypes (columnar whole-year vs massive warm season reproduction) could explain in part the genetic differences observed between the morphotype populations.

The observed differences among morphotype populations in the GC may be due to intrinsic factors (e.g. differences in expulsion times of sperm gametes and larvae, selective recruitment, differences in larvae dispersion), as it has been found in the members of the *Montastraea annularis* complex (Weil and Knowlton 1994; Knowlton et al. 1997). In addition, certain host genotypes from massive and columnar morphotypes were associated specifically with a particular *Symbiodinium* type and depth strongly influenced the frequency of occurrence of particular symbionts in populations of both morphotypes individuals (Paz-García et al. 2009). The possibility of host-symbiont co-evolution in *Porites panamensis* morphotypes is important due high or low light-

adapted symbiont may directly affect the differential success of larvae settling in deep or shallow environments. Further work should address to explain if the latitudinal genetic differentiation and genetic structure morphotypes depend on vertical distribution pattern, clade simbiont and/or intrinsic factors.

Abstract. Genetic structure was studied in the brooding coral *Porites panamensis* along of the Mexican Pacific (MP). We collected in three locations inside of the Gulf of California, two zones at the entrance of the Gulf, and one location at south of MP. Exclusive genotypes in two of six allozyme loci were observed in northern (LGG-1^{DE} and LGG-1^{EE}) and southern (EST-1^{AA} and EST-1^{AB}) populations. All populations presented significant deficits of heterozygotes. These deficits could be for different recruitment and temporal events of larvae expulsion along the MP, high local recruitment and inbreeding by limited dispersion of larvae, and different mortality events by natural disturbances. Cluster analysis of genetic distance showed three groups by geographic proximity: the populations from inside of the GC, two populations from the entrance of the gulf, and the southern population of MP. AMOVA indicated a significant differentiation among the three groups (11.93%, $p = 0.016$). Mean significant F_{ST} value ($F_{ST} = 0.104$, $p < 0.01$) reveled a genetic structure. The oceanic patterns coupled with restricted dispersion of this brooding coral species could be the principal factor that generating the genetic structure observed.

Key words: Population structure, Scleractinian coral, brooding coral, population genetics

Introduction

Porites panamensis is the most abundant coral in the central and north of the Gulf of California and is observed in most coral communities from the Mexican Pacific (Glynn and Ault, 2000; Reyes-Bonilla, 2003). This coral has been reported from 31°N in Mexico to Isla Gorgona (3°N), Colombia (Glynn and Ault, 2000; López-Pérez *et al.*, 2003). *P. panamensis* is a gonochoric species with internal fertilization and colonies begin to reproduce at 5 cm^2 (Glynn *et al.*, 1994). Asexual reproduction by fragmentation has not been observed as important roll in their recruitment (Glynn *et al.*, 1994; Reyes-Bonilla and Calderón-Aguilera, 1994; Paz-García *et al.*, 2009b). Their larvae settle a few meters from the parental colonies (Glynn *et al.*, 1994) and perhaps this reflects a limited capacity of dispersion (Glynn and Ault, 2000). Substrate cover of this coral species in the Gulf of California varies between 1 to 7% of the substrate; in some areas it exhibits a dense covering and in other this totally absent (Reyes-Bonilla and Calderón-Aguilera, 1994; Halfar *et al.*, 2005). ENSO 1982-83 event produced massive mortalities in coral communities of Central America and this species disappeared almost completely in this region (Guzmán *et al.*, 1987; Weil, 1992; Glynn *et al.*, 1994). In Mexico, the damage in the coral communities of this species was lower, and the reproduction and local recruitment of this species only diminished during the ENSO events (Reyes-Bonilla and Calderón-Aguilera, 1994; Medina-Rosas *et al.*, 2005; López-Pérez *et al.*, 2007). Our aim was to determine the genetic structure of the massive coral *P. panamensis* along of the Mexican Pacific (MP).

Material and Methods

Field Work. Collections were conducted from 2004 to 2006 in different areas of the Mexican Pacific (Fig. 1): Bahia de Los Angeles (BLA), Isla San Marcos (ISM), Bahia Concepcion (BCO) and South of Bahia de La Paz (BLP), Punta Arenas (PAV), Isla Redonda (IRD) and La Entrega (LET). The specimens were colleted in shallow coral communities (1-5 m). The coral fragments were frozen in liquid nitrogen, transported to the laboratory, and subsequently stored at –80°C.

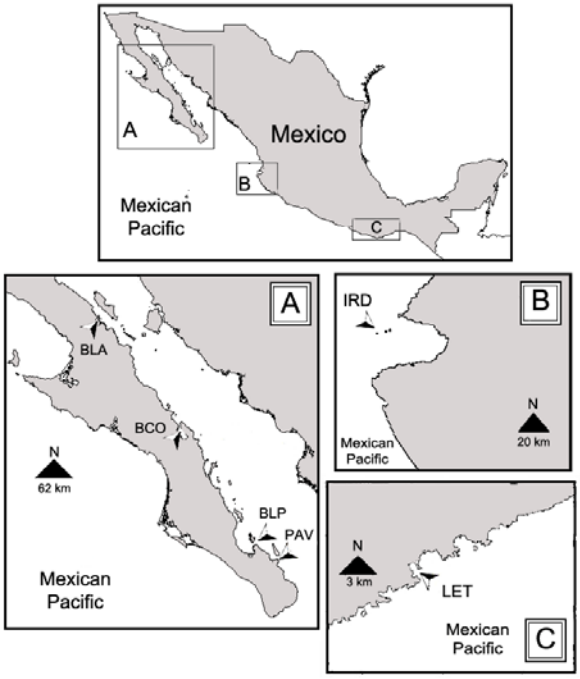

Figure 1: Map of Mexican Pacific showing the collection populations. **BLA** Bahia de Los Angeles, **BCO** Bahia Concepcion, **BLP** South of Bahia de La Paz, **PAV** Punta Arenas, **IRD** Isla Redonda, **LET** La Entrega.

Allozyme Electrophoresis. 3g of superficial tissue-skeleton coral were placed in two vials with 0.7 ml of Stoddart's buffer (Stoddart, 1983; Weil, 1992). The vials were placed in a cold bath of a sonicator and two milliliters of blastate was centrifugated at 2600 *g* for 10 min at 4°C. The resulting supernatant was placed in vials and concentration of total proteins for each sample was determined by Bradford's method (Bradford, 1976) and 25 µg was used for the analysis of each enzyme system (Paz-García *et al.*, 2009b). Allozyme analysis was carried out using the method of Polyacrilamide Gel Electrophoresis (PAGE) by discontinuous gel system in native conditions (Laemmli, 1970; Manchenko, 1994). Four enzyme systems were used: leucine-glycil-glycil peptidase (LGG, E.C.3.4.11.1), malic enzyme (ME, E.C.1.1.1.40), glutamate dehydrogenase (GDH, E.C.1.4.1.3) and esterase (EST, E.C. 3.1.1.1).

Statistical analysis. Genetic variability was calculated for each population using BIOSYS-1 software package (Swofford and Selander, 1981). Unbiased genetic distances (Nei, 1978) were used for cluster analysis, as implemented in TFPGA (Miller, 1997). We performed an analysis of molecular variance (AMOVA) to compare genetic similarity among three groups: I) populations from the GC, II) entrance of GC, and III) the population from the south of MP. P-values were calculated from a random permutation test with 16 000 replicates (Excoffier *et al.*, 1992). The level of genetic heterogeneity was estimated by F_{ST}. We calculated pairwise F_{ST} estimates between each pair of populations. F_{ST} were tested for difference from zero permuting (10 000 replicates) alleles between samples with exact G-test (Goudet *et al.*, 1996), as implemented in FSTAT v. 2.8 (Goudet, 1995). We applied a sequential Bonferroni correction to reduce the chance of type I errors (Rice, 1989).

Results

Five loci were detected using four enzyme systems. We observed exclusive genotypes from the most northern (BLA: LGG-1^{DE} and LGG-1^{EE}) and southern (LET: EST-1^{AA} and EST-1^{AB}) populations (Anexus I). The allelic diversity at each location ranged from 2.4 to 2.8 (Fig. 2a). The observed heterozygosities were lower that the expected under Hardy–Weinberg equilibrium in all populations, ranging from 0.106 to 0.260 (Fig. 2b).

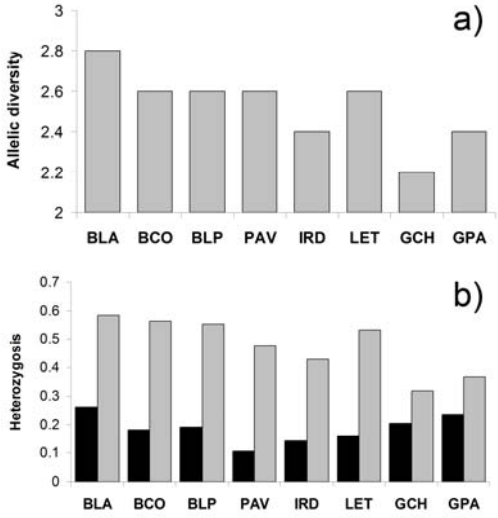

Figure 2. a) Allelic diversity. b) Heterozigosis. Observed and Expected Heterozigosis, black and gray, respectively. Population abbreviation as in Fig. 1. **GCH** Gulf of Chiriqui and **GPA** Gulf of Panama (data from Weil, 1992).

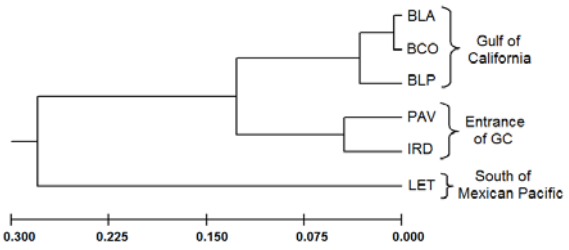

Figure 3. UPGMA dendrogram based on Nei´s (1978) unbiased genetic distance. Population abbreviation as in Fig. 1.

Cluster analysis based on Nei's (1978) unbiased genetic distance, showed three groups by geographical proximity: (I) the populations from inside of the GC, (II) two populations from the entrance of the Gulf, and (III) the southern population of MP as other cluster (Fig. 3). AMOVA indicated a significant differentiation among the three groups (11.93%, p = 0.016), among populations within groups (3.38%, p = 0.036), and within populations (84.68%, p < 0.001). Mean significant F_{ST} value (F_{ST}=0.104, p < 0.01) was observed for the massive populations of *P. panamensis*. Pairwise F_{ST} estimates revealed significant differences among populations along the MP, except the populations from inside of the GC (Table 1).

Table 1. F_{ST} values (below diagonal) and p values (above diagonal) for the massive coral *Porites panamensis* from the MP. Population abbreviations as in Figure 1. F_{ST} were tested for difference from zero permuting (10 000 replicates) alleles between samples with exact G-test (Goudet *et al.*, 1996). NS = not significant, * p < 0.001 after Bonferroni correction.

Discussion

Allelic diversity in two populations of *P. panamensis* from the Panamanian Pacific showed values ranged from 2.2 to 2.4 alleles per locus (Fig. 2a; Weil, 1992). For the present work, most populations of *P. panamensis* from the MP presented slight higher values (2.4-2.8). The observed heterozygosities, ranged from 0.205 to 0.236 in two populations of *P. panamensis* from Panama (Fig. 2b; Weil, 1992). All populations of *P. panamensis* from the MP were slight higher that this (Fig. 2). During the 1982-83 ENSO event, populations of *P. panamensis* from the Panamanian Pacific suffered severe mortalities that caused their disappearance almost completely (Guzmán *et al.*, 1987; Glynn *et al.*, 1994). In Mexico, the recruitment of this species diminished during the ENSO events (Reyes-Bonilla and Calderón-Aguilera, 1994), but contrary to the reefs of Central America, this species suffered lower mortalities, it has continued reproducing and their larvae have recruited locally (Medina-Rosas *et al.*, 2005; Mora-Pérez, 2005; López-Pérez *et al.*, 2007). Genetic variation observed among the populations of *P. panamensis* from the Mexican and the Panamanian Pacific, may be due to the difference in the mortality presented in both regions, since it has been mentioned that the heterozygosities diminishes fast when the size population is reduced (Gillespie, 1998).

A deficit of heterozygous is characteristic of several coral species and several explanations for such heterozygosity deficits have been proposed (Ayre *et al.*, 1997; Ayre y Hugnes, 2004). Heterozygousity deficits observed in populations of *P. panamensis* along of the MP could be due to different recruitment events of cohorts and mixes of adult colonies from diverse coral communities (Medina-Rosas *et al.*, 2005; López-Pérez *et al.*, 2007), different temporal events along the MP when larvae expulsion takes place (Vizcaíno-Ochoa, 2003; Mora-Perez, 2005; Rodríguez-Troncoso, 2006; Paz-García *et al.*, 2009b), high local recruitment and inbreeding by limited dispersion of larvae (Glynn y Ault, 2000); and different mortality events by natural disturbances (Reyes-Bonilla *et al.*, 2002).

The dendrogram based on Nei's (1978) unbiased genetic distance showed three groups by geographic proximity (Fig. 3). Our data supports the similarity among the populations inside of the GC and the differentiation between the entrance of the GC (PAV y IRD), and the southern population of the MP (LET). Same pattern of population subdivision in the MP was observed in *Pocillopora damicornis* (Chávez-Romo *et al.*, 2008). These results suggest that the inside populations of the GC may be a group more homogeneous genetically, while the populations of the entrance of the GC (PAV y IRD) and southern of MP (LET) present a genetic differentiation that may be due at the high frequency of natural phenomenon (e.g. hurricanes, upwelling zones and mortality by ENSO events).

Genetic structure among populations of *P. panamensis* in the MP was supported by mean AMOVA (11.93%, p = 0.016) and significant F_{ST} value (F_{ST}=0.104, p < 0.01). Previous studies in the GC and MP have found population subdivision in different marine invertebrates and fishes groups (De la Rosa-Vélez *et al.*, 2000; Riginos y Nachman, 2001; Valles-Jimenez *et al.*, 2005). Genetic structure was reported in other coral species along of the California cost (*Balanophyllia elegans*, mean F_{ST} = 0.195; Hellberg, 1996), and along the MP in the species *Pocillopora damicornis* (F_{ST} 0.153, Chávez-Romo *et al.*, 2008) and *Pavona gigantea* (Φ_{ST} 0.10-0.20; Saavedra-Sotelo, 2007). Several factors may help generate population genetic subdivision in the MP, including biogeography, geographic distance, habitat discontinuities, current direction, and differences in the environmental conditions (e.g. temperature, tide, eutrophic conditions by upwelling zones), could result in different evolutionary histories among populations (De la Rosa-Vélez *et al.*, 2000; Riginos and Nachman, 2001; Halfar *et al.*, 2005; Valles-Jimenez *et al.*, 2005). We suggest other factors that could be generating the pattern observed: differences in

reproductive seasons among coral communities along the MP (Paz-García *et al.*, 2009b; Chávez-Romo *et al.*, 2008), selection of resistance genotypes due at the differential blanching and mortality events (Reyes-Bonilla *et al.*, 2002), the presence of different symbiont clades in one same host species and the possibility of different combination between host and symbiont along the MP, could be represent different opportunities to support low light conditions and high level of environment stress (LaJeunesse *et al.*, 2007a, b; Paz-García *et al.*, 2009a, b), and the existence of long sand barriers and mangroves communities that may limit the larval dispersion between coral communities (Glynn y Ault, 2000). Also, the oceanic patterns coupled with restricted dispersion of brooding coral *P. panamensis* could be the principal factor that is generating the genetic structure observed on the populations in the MP. However, detailed studies in ecology, reproduction and genetics are necessary to understand better the relationships between the coral populations in the MP.

Acknowledgement

We thank the program of Costal Oceanography of the Facultad de Ciencias Marinas and the Instituto de Investigaciones Oceanológicas of the UABC for financial support of the first and third authors to attend the 11th ICRS. The first and third authors were supported by CONACYT Master of Sciences scholarships (numbers 198821 and 198888, respectively). This work was also made possible by funding from CIBNOR-UABCS project (MPHC y HRB), Project AWARE Foundation (DAPG) and the Semarnat project 2002-c01-0605 (RALP). We thank at the work group of the Parque Nacional Islas Marietas. We also thank Karina Xolaltenco, Luis Lombardo and Diana Sánchez by their help in lab.
